BRITISH FOREST TREES.

British Forest Trees. By J. Nisbet, D.Œc. (London: Macmillan and Co., 1893.)

WITH the exception of Dr. Schlich's able "Manual of Forestry," of which two volumes are now before the public, the English student of arboriculture has for many years past been almost entirely dependent on French and German works for recent information as regards the progress of that part of the art of forestry which deals with the cultivation of our native and introduced trees. The present work is a praiseworthy attempt to remedy this state of dependence, and to provide British foresters with a text-book which shall give the results of modern experience in an English dress.

The plan of the work is simple and to the point. After briefly summarising the history of British forests—too briefly, perhaps, will be the opinion of some—the author proceeds to enumerate the chief forest-trees of our country. To those who miss any reference to some of the minor and unimportant woody plants growing in our hedges, it should be pointed out that the principal forms met with as underwood or coppice are treated separately at the end of the book; while those who feel any surprise at the introduction of several European (but not British) and American trees, especially conifers, should bear in mind that these have been so much planted in England and Scotland of late years, that no work on British forestry can afford to neglect them. Mr. Nisbet seems to have carefully stated what is necessary in this connection.

The next sections of the book deal with the important and very interesting subjects of forest growth in relation to soil, the growth of timber in general, and comparative considerations regarding the growth of forest trees.

It may perhaps be doubted whether the author has succeeded in stating anything new in this connection, beyond what has already been put forward in other text-books, and it is admitted that the sources of the information are almost entirely continental, especially German. Perhaps the chief merit of these parts of the book is the author's manner of putting the facts; for, on the whole, they read well and consecutively, and no student of sylviculture can fail to profit by them.

Sylviculture—and the same is true of forestry in general—is a subject about which much can be written and said, and the temptation to be prolix is great, with such materials. The author's conscientious acknowledgments of the sources of his quoted tables and experimental data may certainly be put to his credit; and although we may doubt whether any practical forester will accept all the statements unreservedly—for foresters, like farmers, are often somewhat apt to generalise too widely from individual experience in one part of a country—few will deny that Mr. Nisbet has succeeded in putting forward very plainly a large amount of information about the sylvicultural aspects of forests in general. The chief fault to be found with this part of the book is, perhaps, that the experience on which the statements are based is almost entirely German, whereas there is really a great deal to be said about the behaviour and treatment of forests in this climate as well.

The principal, and by far the greater part of the book however, is concerned with the treatment of the several species of forest trees in detail. Here, again, the British cultivator will doubtless raise the objection that the author almost entirely confines himself to the experience of foresters in Germany; but it is more and more borne in upon the reader that there is reason in this, in so far that several really great authorities on the cultivation of trees have arisen in that country, whereas it would be difficult to name any in this country.

Be this as it may, there can be no question that Mr. Nisbet has succeeded in collecting a very large amount of valuable information regarding the experience of foresters as to what trees will grow in certain situations, how fast they may be expected to grow there, and how much timber they may be made to yield if properly treated; as to what trees should preferably be grown together in mixed forests, and why such and such mixtures are undesirable; and, further, to what dangers given

species are exposed when grown in quantity, and so forth.

Some of the sections are notably long, and the author gives signs of the discursive habit incidental to those who read and transcribe much from German text-books; moreover, there are sentences which betray the German method in their construction, and there is a distinctly Teutonic sound about some of the terms and short phrases, such as "soil-improving," "free enjoyment of light and air," "above-sketched method," "equal-aged crops," and so on.

With all its faults of diffuse writing, and a certain amount of repetition, the work is likely to be valuable to students of forestry in this country, as setting forth the experience of German and other continental authorities in the growth and tending of mixed and other forests. One or two misprints have come under our notice, *e.g.* an *f* has dropped on p. 161; and should not "prunosa" (p. 328) be *pruinosa?* Again, why adopt the antiquated term "Scots Pine"?

ASTRONOMY OF THE NINETEENTH CENTURY.

A Popular History of Astronomy during the Nineteenth Century. By Agnes M. Clerke. Third Edition. (London: A. and C. Black, 1893.)

DURING the six years that have elapsed since the publication of the second edition of Miss Clerke's classical history of astronomy, new light has been thrown upon a number of old ideas, and many important discoveries have been made. It became necessary, therefore, for the authoress to revise her work, to add here, and substitute there, and in all cases to incorporate the recently-acquired facts without breach of continuity. There is no suggestion of interpolation, and nothing but praise can be given for the manner in which the selected material has been assimilated.

Attention may be directed with advantage to one or two points. On p. 199 a description is given of the luminous outburst observed upon the sun in September, 1859. The occurrence is supposed to have been followed immediately by a break in the magnetic records at Kew, and every astronomical text-book instances it in evidence of the sun's ability to disturb terrestrial magnetism. Miss Clerke's words with reference to the matter are as follows, the italicised expression being her own:—"*At the very instant* of the solar outburst witnessed by Carrington and Hodgson, the photographic apparatus at Kew registered a marked disturbance of all the three magnetic elements." Now, at a meeting of the Physical Society in 1886, the late Mr. Whipple said that from an examination of the magnetic curves, he believed "the very slight notch in the record, many similar to which have occurred since, was of an accidental nature, and a mere coincidence." (NATURE, vol. xxxiii. p. 621.) Further, in a letter to the writer of this notice, Mr. Whipple remarked "it was merely an insignificant wriggle of the curves that was recorded at the time of the Carrington and Hodgson observation, and the great magnetic storm did not commence for some fifteen hours later." Miss Clerke would do well to mention Mr. Whipple's contention in a future edition, and if she will look at the traces and decide the point—accepting Sabine's interpretation of a magnetic disturbance (*Phil. Trans.* vol. cliii. p. 274), she would do a good work. Possibly the coincidence will be disproved before the appearance of the next edition. Tenets of belief accepted quite as implicitly have had to be given up in the interim between the publication of the second edition and the one before us. Thus, in the former edition we read (p. 437) "the conspicuous bright line of the Draco nebula was found to belong very probably to nitrogen"; whereas the present rendering is "the conspicuous bright line of the Draco nebula, although nearly accordant in position with one belonging to nitrogen, has since proved to be distinct from it." But for the suggestion that the chief nebular line had its origin in magnesium, the nitrogen origin would, in all probability, still be accepted. The search for truth initiated by the suggestion, has thus borne good fruit in disposing of the nitrogen-origin "for ever and for aye." One begins to wonder why the idea remained above suspicion for so many years. It is well known that the green line of nitrogen is double, and it now appears that the magnesium fluting is really nearer the true position of the chief nebular line than the nitrogen double. What is more, the magnesium origin was indicated by laboratory experiments, whereas nitrogen had nothing but an approximate coincidence to support it.

In connection with the spectra of nebulæ it may be pointed out that no mention appears to be made of the observation of the discontinuous character of the spectrum of the Andromeda nebula (*Roy. Soc. Proc.* vol. xlv. p. 216), and of the white nebula in Draco, G.C. 4058 (*Ibid.* vol. xlviii. p. 219). This is to be regretted, for the observations are of importance, and, in all probability, many of the spectra now classified as continuous are only irregularly so; hence a study of these minute differences of brightness may very considerably add to our knowledge of stellar constitution. We also fail to find a description of Prof. Boys' work on the heat of the moon and stars (*Roy. Soc. Proc.* vol. xlvii. p. 480).

There are seventy-two more pages in the third edition than in the previous one, and five plates have been added. An extremely useful set of tables of astronomical data has also been included. The chronological table has, of course, been brought up to date, and it gives an excellent digest of the work that has been done between March 1774 and April 1893. It can hardly be said, however, that the strict impartiality which should characterise a history of astronomy has been exercised when an event of such local interest as a "Lecture by Dr. Huggins, on Nova Aurigæ, at the Royal Institution," is recorded as having taken place on May 13, 1892, while the announcement on February 8, 1892, of the duplex nature of the lines in the spectrum of the same Nova is unmentioned in the table.

The merits of the volume are now so well known that it is quite unnecessary to expatiate upon them. It seems to us, however, that if Miss Clerke were more a historian and less a partisan, her work would be of higher value.

OUR BOOK SHELF.

Inorganic Chemistry for Beginners. By Sir Henry Roscoe, F.R.S., assisted by Joseph Lunt. (London: Macmillan and Co., 1893.)

Everyone recognises the necessity for having works upon elementary science written by men in thorough touch with their subject. It is with some satisfaction, therefore, that we notice this book, in which Sir Henry Roscoe clearly expounds the elementary principles of chemistry, and describes some of the non-metallic elements and their more important compounds. The book differs from the author's well-known "Lessons in Chemistry" in arrangement and in style, and is far better suited to the tyro in chemistry. In fact, it is adapted to suit the requirements of the syllabus of the Department of Science and Art, and both teachers and students under the Department will benefit by its introduction. There are twenty-one lessons in the book, each complete in itself. At the end of each lesson is a brief summary and a set of questions bearing upon the subjects treated. Believing with all educationalists that principles only become apparent when they are reflected by facts, the author illustrates each step with an experiment. One hundred and eight illustrations elucidate the text, and though many of them are of the ordinary stock character (which is, perhaps, unavoidable in a book of this kind) a fair proportion are from new blocks. In every respect the book is a good one, and contains the kind of knowledge that should be imparted to all beginners of science.

The Chemistry of Fire. By M. M. Pattison Muir. (London: Methuen and Co., 1893.)

The fact that this book belongs to a University Extension Series vouches for the popular character of the contents. Extensionists should welcome Mr. Pattison Muir's contribution to their literature, for it represents the work of a practical teacher, and combines accuracy with simplicity. It is now generally conceded that the best way to teach chemistry is to deal first with common occurrences and things, and finally to generalise. Let a student once obtain a correct notion of the changes of composition that happen in the burning of a candle, and he can comprehend all chemical changes. We therefore commend the book before us to the notice of committees and organisers of technical education, for it contains just the kind of knowledge that should be imparted to all students under their guidance. Like the majority of the volumes in the series to which this one belongs, the illustrations are few and very sketchy. On this account it will be difficult for the home-reader to get a clear conception of many of the experiments.

Solutions of the Exercises in Taylor's Euclid I. to IV. By W. W. Taylor, M.A. (Cambridge: University Press, 1893.)

By the publication of these solutions, Mr. Taylor has furthered very considerably the usefulness of the book written by his brother. In the book he has worked out very fully all the problems, and has arranged the text in such a form as to be thoroughly intelligible to any student. Where several problems were of a similar character, it has been thought expedient to adopt a different mode of solution, while in some cases duplicate solutions have been given. Extension of theorems have here and there been inserted, and a few additional exercises will also be found to have been interpolated. By the adoption of a simple notation, reference can be directly made to the problems in the "Pitt Press Euclid." Both teachers and taught will find that they have a very useful companion to the above-mentioned book, while the latter will be very much enlightened in the art of solving many problems.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Recent Glaciation of Tasmania.

In a paper read before the Royal Society of Tasmania in June last, Mr. R. M. Johnston, F.L.S., gives a sketch of what is known of the glaciation of the island, or rather of the western portion of it, for no indications of glaciers appear to have been discovered in the eastern half. This difference is supposed to be due to the fact that on the western side of the island the rainfall is from 50 to 76 inches annually, while in the central valley it is but little over 20 inches. Indications of glaciation among the western mountains were noticed by Mr. Charles Gould, Government geologist, about forty years ago, and from information received from him through the late Chief Secretary of Tasmania, the Hon. J. R. Scott, Mr. Johnston took up the inquiry, and for many years has made explorations in the western plateaus and mountains. Mr. C. P. Sprent was another explorer who published some account of the glacial phenomena in 1886, while more recently Mr. T. B. Moore and Mr. Dunn have recorded similar observations. Mr. A. Montgomery, the present Government geologist, has also just published a paper on the same subject.

Mr. Johnston tells us that he has personally explored the whole of the western mountains, from the Picton and Craycroft Rivers, southern branches of the Huon, in the extreme south, along the mountain ranges forming the western border of the central plateau, quite through to Emu Bay on the north coast; and that he has found the clearest evidences of glaciation in almost every valley throughout this great extent of country. From the Arthur Range in the south to Mount Bischoff in the north, are numerous moraines, *roches moutonnées*, tarns and lakes in great abundance, polished and striated rock-surfaces, and numbers of true erratics. Near the sources of the Franklin River, under Mount Hugel, and only six or seven miles west of Lake St. Clair, are Lakes Dixon and Undine, of which Mr. Johnston writes:—"The valley of Lake Dixon is *par excellence*, the ideal of a perfect glacier valley. No one, however ignorant of glacial action, could in this neighbourhood gaze upon these beautiful scooped, or rather abraded lakes or tarns, the snow-white, polished, billowy, and cascade-like *roches moutonnées*, composed of quartzites, on the upper margin of Lake Dixon, together with the tumbled moraines and large erratics on the lower banks—at a level of about 2000 feet—without being impressed with the idea that its singularly characteristic features must have been produced by the slow rasping flow of an ancient river of ice."

Further north, the Murchison, Macintosh and Huskisson rivers, all branches of the Pieman River, contain similar glacial markings; and Mr. Dunn has recently described others of the same character about Lake Dora, nearer to the west coast. The latter observer lays special stress on the rounded planed and scored rocks, on hard quartzite and conglomerate rocks rounded and polished, on numerous tarns in rock-basins, on moraines covering hundreds of acres, and on numerous huge erratics and perched blocks. (See Annual Report of the Secretary for Mines, Victoria, 1893, p. 21.)

Mr. T. B. Moore states that he found the rocks polished and striated within 25 feet of the top of Mount Tyndall, or 3850 feet above the sea, a sufficient indication that the great central plateau at an average elevation of nearly 4000 feet must have been buried in ice or *névé* to a considerable depth, and have formed the feeding ground for the glaciers, whose effects are so visible in the adjacent western valleys. The Tasmanian geologists are united in the belief that the glaciers never reached the coast or descended much below the 2000 feet level, and that the ice did not extend to the central valley or the eastern side of the island. They therefore speak of it as a *glacier*, not a *glacial* period, the conditions being somewhat similar to those of the Alps at the present time; but, owing to the great difference in the rainfall, there was a more marked contrast between the western and eastern districts, while the lofty central plateau afforded a much more extensive snow-field than Switzerland now possesses.

The facts here stated on the authority of Mr. Johnston, sup-

ported by those of three other observers, two of them being the Government geologists, render more singular the statements of Messrs. Officer and Spencer (NATURE, June 29, p. 198) as to their not finding any traces of glaciation in the country around Lake St. Clair, which they explored for a month. Lake Dixon, which Mr. Johnston describes as presenting all the evidences of glaciation in their fullest development, appears to be less than ten miles from the lower end of Lake St. Clair, according to the best map I can refer to; while Lake Petrarch, which Mr. Officer describes as seeing from the top of Mount Olympus, lies between the two in the Cuvier valley, and is also mentioned by Mr. Johnston as being within the highly-glaciated region. It is quite possible that the lakes on the great plateau may be due to damming up, owing to movements of the superficial gravels and clays by the ice or *névé* sheet; but there are evidently an abundance of small valley-lakes and tarns in the western valleys so surrounded by all the marks of extensive glaciation as to render it almost certain that they are true ice-eroded rock basins. It is much to be wished that a more detailed account of this interesting district, with a good map showing all the mountains, lakes, and valleys referred to, would be given us by one of the local geologists. ALFRED R. WALLACE.

The Supposed Glaciation of Brazil.

MR. WALLACE observes in his letter on this subject, published in NATURE (vol. xlviii. p. 589), that "no authoritative disproof has yet been given of the exceedingly strong and positive statement of Agassiz and Hartt."

I confess to my mind the matter had seemed disposed of by the interesting discussion of the subject to be found in the "Notes of a Naturalist in South America" (1887), by the late Mr. John Ball, F.R.S. This experienced and accurate observer arrived at the conclusion from a study of the phenomena on the spot, that they could be sufficiently accounted for by subaërial denudation (see, in particular, pp. 313–8).

In the following passage he rejects the agency of glacial action as definitely as his habitual caution and modesty would allow:—

"I was unfortunately not acquainted at that time with the observations made near Tijuca by Prof. Alexander Agassiz, which appear to him to give evidence of glacial action in this part of Brazil. It would be rash, especially for one who has not been able to examine the deposits referred to, to controvert conclusions resting on such high authority; but I may remark that the evidence is confessedly very imperfect, and that the characteristic striations, either on the live rock or on the transported blocks, which are commonly seen in the theatre of glacial action, have not been observed. I lean to the opinion that the deposits seen near Tijuca are of the same character as those described by M. Liais[1] as frequent in Brazil. The crystalline rocks are of very unequal hardness, and while some portions are rapidly disintegrated, the harder part resist. The disintegrated matter is washed away, and the result is to leave a pile of blocks of unequal dimensions lying in a confused mass." (P. 342.) W. T. THISELTON-DYER.

Royal Gardens, Kew, October 23.

The Nativity of Rama.

I HAVE been much interested in the letter of "Kanhaiyalal," which appears in your issue of August 31. I fully agree with him in the view taken in regard to the verification of dates by astronomical methods, and it really does seem somewhat singular that the example of Sir William Jones, the pioneer of Orientalism in Europe, should have been entirely neglected by his learned colleagues and successors in this department of research. From many considerations it must be obvious that wherever mention of planetary "yogams" or conjunctions, siderial and lunar positions, &c., are given in the text of any classical work, they are to be preferred to any arguments drawn merely from literary style and other empirical data—so much relied upon by Orientalists and scholars generally—when the question is one of a calendaric date.

I have endeavoured to work out the calculation of Rama's birth figure. In *Ramayana* is the following slokam, or stanza, referring to Rama's birth:—"*Chaitre navamike tithau Nakshatre aditi daivatye sewochha samstheshu panchasu Griheshu karkate lagne.*" From this we learn that Rama was born in the ninth day of the Moon's age, and that five planets were in their exaltation signs, the rising sign (*lagnam*) being Cancer (of the Hindu Zodiac). The planets' places are given in Section 18 of the English translation of *Ramayana*, by Manmatha Nath Dutt, M.A., in the following words:—

"And then, when six seasons had rolled away after the completion of the Sacrifice, in the twelfth month, on the ninth lunar day, under the influence of the Punarvasu asterism, when the Sun, Moon, Saturn, Jupiter, and Venus were at Aries, Capricorn,[1] Libra, Cancer, and Pisces, and when Jupiter had arisen with the Moon at Cancer, Kaushalya gave birth to that lord of the universe, bowed unto by all the worlds, Rama, &c."

It may be well to state for the benefit of those not acquainted with the Hindu zodiac, that an asterism includes $13^\circ 20'$ of the ecliptic circle, and consequently there are twenty-seven asterisms in all. Of these, Punarvasu is the seventh. The zodiac commences with the asterism *Aswini*, and the fixed star *Revati* is the point from which enumeration of longitude begins. This star is said to have been coincident with the equinoctial point *To* in the year 3600 of the Kali Yuga, *i.e.* 498 A.D.

The last conjunction of Saturn and Jupiter in the sign Libra was in K.Y. 4224, and the one previous in K.Y. 1344; and from this we must subtract three Signs to bring Jupiter into Cancer (its exaltation). This equation referred to the "period" of Jupiter, *i.e.* twelve years, gives three years to be subtracted. The year K.Y. 1341, therefore, would see Saturn in Libra, and Jupiter in Cancer as required.

The Moon being nine days old at the birth of Rama, and its motion in respect to the Sun being 12° per day, its distance from the place of conjunction must be taken as over 96°. But it is stated in the *Slokam* that the Moon is in Punarvasu, and as this asterism ends at $93^\circ 20'$ from the star Revati, it is evident that the conjunction of the luminaries took place in the twenty-sixth degree of *Minam* or Pisces; and that on the ninth day the Moon was in the first degrees of Cancer (Hindu *Kartaka*) and the Sun in the fifth degree of Aries (Hindu *Mesham*).

To determine the date of this planetary epoch we must have recourse to the Ayauámsha, the distance between the fixed star Revati and the Vernal Equinox. The Hindus compute this to be $54''$ per year, and in accordance therewith their month of Mesham (Aries) begins on April 11. At the present time Revati is behind the Equinox, but in K.Y. 1341 it was in front of it, regarded by the order of the Signs. The calculation for K.Y. 1341, according to Suryasiddhauta, is:—

$$(3600 - 1341) \times 54'' = 33^\circ 53' 6''.$$

Referring this to the Equinox, it gives a point corresponding to the twenty-seventh degree of Aquarius in *our* zodiac, which was the point at which the Hindu zodiac began in the year K.Y. 1341; and from this we must take 4° to bring us to the 26th of *Minam*, wherein the Sun and Moon were conjoined at the birth of Rama. The result is the twenty-third degree of Aquarius in our zodiac.

We have already obtained the year K.Y. 1341 from the positions of the planets Jupiter and Saturn, and we may now apply this luni-solar position as a test.

On February 11, 1888, the Sun and Moon were conjoined in the twenty-third degree of Aquarius. This date corresponds to the beginning of the tenth month of the K.Y. year 4989. Applying the Metonic cycle, we find that a conjunction of the luminaries also took place in the twenty-third degree of Aquarius (Hindu twenty sixth *Minam*) in K.Y. 1341, thus:—

$(4989-1341) \div 19 = 192$ *exactly*. I have not yet made reference to the position of Venus as given in the above *Slokam*, but I think there is strong evidence of this being the correct epoch, and I think it not unlikely that Venus had less than 30° west longitude of the Sun, in which case it would be in the Hindu sign corresponding to our Pisces, *i.e. Minam*, as required by the *Slokam*.

This epoch corresponds to noon (local time) February 10, 1761 B.C., disregarding the change of Style; and, if correct, may be the time of the birth of Rama; but on this point I should not care to judge too hastily, for in view of the recurrence of these positions at some earlier or later date, we have no evidence which should lead us to select one rather than another epoch.

One thing strikes me as sufficiently curious to record in

[1] See his valuable work, "Climats, Géologie, Faune et Géographie Botanique de Brésil."

[1] This should be *Cancer*, not Capricorn, as is seen from the fact of the Moon's rising with Jupiter.

this connection, viz. that in Sáukaravijaya of Vidyaranya, the same positions are given for the planets at the birth of Sáukarácharya, with the exception of the Moon, which is in Arthra, *i.e.* Gemini, 6° 40′ to 20° 0′ of the Hindu zodiac. These positions of the Sun, Moon, Jupiter, and Saturn took place on the 1st of *Mesham*, Kali Yuga 4221, corresponding to March 30, A.D. 1119, without change of the present style.

I am afraid, however, that these dates will hardly suit my Hindu friends, whose devotion to these great personages gives them a sense of "distance" which is best satisfied when expressed in *years!* I give these notes, however, for what they may be worth.

Adyar, Madras. WALTER R. OLD.

NOTE.—According to the Suryasiddhanta rules for computing the longitudes of the planets, I find that Mars was in Capricorn, its "exaltation" Sign, in the month of *Mesham*, K.Y. 1341, as required by the data given for Rama's epoch, its longitude in the Hindu zodiac being Capricornus 13°.—W. R. O.

On the Latent Heat of Steam.

SINCE the invention of M. Berthelot's extremely elegant and simple apparatus, described in his "Mécanique Chimique," vol. i. p. 288, the approximate determination of the latent heat of vaporisation of liquids has become comparatively easy. The exact evaluation of the correction due to the heating of the calorimeter from extraneous sources is, however, a matter of considerable difficulty with the original form of apparatus. The correction is necessarily calculated from data supplied by the thermometric observations made previously to, and after, the actual condensation of the liquid has taken place. For this calculation to be as simple and satisfactory as possible, it is essential that during the whole experiment the temperature of the bodies in the immediate neighbourhood of the calorimeter shall remain approximately constant. In M. Berthelot's method of determination this condition is however not strictly fulfilled. For during the "preliminary period," although the flame is lighted over the calorimeter, the liquid in the flask has not yet begun to boil, so that the radiation to the calorimeter varies, and during the "final period" the flame is extinguished and no further heat reaches the calorimeter from this source. Also during the beginning of the "middle period," a considerable amount of liquid which has been volatilised from the flask at a temperature below its boiling-point, reaches the worm and is there condensed. We therefore modified the apparatus in such a way that the flame was at a constant height and the liquid was boiling *during the whole time of the experiment*, including both the preliminary and final periods. We found that under these circumstances, with a rise of 3° or 4° in ten minutes, the Regnault-Pfaundler correction is perfectly accurate. We propose shortly to publish a complete description of our apparatus, and shall not therefore go into details at present. It differs mainly from that of M. Berthelot, by the insertion in the interior of the boiling flask of a glass valve, which is opened when the rise of the thermometer in the calorimeter has become steady, and closed when sufficient liquid has been condensed in the worm. The vapour during both the preliminary and final periods passes into a reversed condenser.

Our main reason for this communication is to record the somewhat remarkable results obtained with water, and to ask if any of your readers can give information as to any accurate work upon the latent heat of steam published since that of Regnault (*Mémoires de l'Académie des Sciences*, t. 21) in 1847.

We give the results of five experiments (done at pressures differing but little from 760 mm.), which are still subject to certain corrections not exceeding ± 1 unit.

	Wt. of water condensed in grams.	Time of condensation in minutes.	Rise of temp. in calorimeter in deg. C.	Latent heat of steam (L).
(1)	10·122	7½	3·491	525·6
(2)	12·546	15	4·416	524·7
(3)	9·278	8	3·235	526·6
(4)	9·854	7	3·439	525·0
(5)	2·742	6	·991	523·9

It will be noticed that in experiment 5, where the amount of water condensed was purposely reduced, so as to increase as far as possible the experimental error, the result obtained differs but slightly from the mean. This mean, 525·2 (omitting experiment 5, 525·5) is over 2 per cent. lower than that of Regnault. The thermometer used was one divided into fiftieths of a degree, by Baudin, and was compared with a thermometer calibrated at the International Bureau of Weights and Measures. Every precaution was taken to ensure accuracy of reading.

We have sought for confirmation of our results in the indirect determinations of other observers. If we insert the latest values for the specific volume of steam at 99·6° given by Perot (*Ann. Chim. et Phys.* [6] 13, p. 159) and for the mechanical equivalent of heat by Griffiths[1] (NATURE, vol. xlvii. p. 476) in the thermodynamic formula,

$$L = \frac{T}{J}(S - S')\frac{dp}{dt},$$

we find the number 527·43 for the value of L at 99·60° C.[2] The number given by Regnault for 100° C. is 536·7. We have also selected from the numerous results obtained by Joly (*Proc. Roy. Soc.* vol. xli. p. 358) with his steam calorimeter those relating to silver, which is a substance easy to obtain in a state of purity. If we take the number given by Regnault for the specific heat of silver, we find his own determination of the latent heat of steam confirmed. On the other hand the concordant numbers for the specific heat of silver, given independently by Kopp and Bunsen, lead to a result about 1½ per cent. lower than that of Regnault.

The complete discussion of such results, however, is a matter of great difficulty owing to the uncertainty which prevails with regard to the specific heat of water. We have not as yet succeeded in discovering any constant error capable of explaining the discrepancy between our result and that of Regnault, but further experiments are now in progress.

The question, as need hardly be pointed out, is of considerable practical importance in connection with problems relating to the steam engine.

P. J. HARTOG.

Artificial Amœbæ and Protoplasm.

IN No. 1251 of NATURE, Dr. John Berry Haycraft has written a review on Prof. O. Bütschli's investigations of microscopic foams and protoplasm.

The biological parts of the contribution I may leave my colleague, Prof. Butschli, to answer, but as my investigations are also mentioned, and my name several times quoted, though always mis-spelled as "Nuincke," instead of Quincke, I may perhaps be allowed to call attention to the fact that I, not Prof. Bütschli, as the reviewer asserts, was the first who tried to explain the movements of amœbæ and protoplasm by physical laws, by the periodical spreading of a soap solution. In 1879 I explained the voluntary formation of an emulsion observed by Prof. Gad, and the amœboid movements of oil-drops by the periodical spreading of a soap solution upon the common surface of oil and water, and I said "that foam is an emulsion of air instead of oil, and that the durability of foam depended on the same conditions as the durability of an oil emulsion."[3] In a continuation of these investigations I explained in the year 1888 the movements of protoplasm by the same physical principles, making the supposition that it was intermixed with thin oil-films, and in the cells of plants, surrounded by an oil-coat.[4] I therefore believe I was the first to point to the foamy structure of protoplasm, which was later on further investigated by Prof. Bütschli.

Is Dr. John Berry Haycraft acquainted with my investigations, and from whence does he deduce the right of calling them "toys for the physicist"? They form the conclusion of a series of researches on capillarity which I began 37 years ago, and by which I, for the first time, showed that surface-tension is considerably altered by layers of a foreign substance of far less thickness than 1/10 of a light-wave; for the first time, also, the

[1] We understand that Mr. Griffiths' number is still subject to a slight correction, but that this does not amount to 1 part in 1000.

[2] $\frac{dp}{dt}$ was calculated from Roche's formula quoted by Hirn, Théorie Mécanique de la Chaleur, *t.* I. p. 325.

[3] G. Quincke, "Ueber Emulsionsbildung und den Einfluss der Galle auf die Verdanung" (*Pflüger's Archiv.* 1879. p. 144).

[4] G. Quincke, "Ueber periodische Ausbreitung an Flüssigkeitsoberflächen und dadurch hervorgerufene Bewegungserscheinungen" (*Sitzungsber. der Berliner Akad.* 12, 7, 1888. *Wiedem. Ann.* 35, p. 580-642, 1888). "Ueber Protoplasma bewegungen und verwandte Erscheinungen" (*Tageblatt der 62 Versammlung Deutscher Naturforscher und Aerzte*, Heidelberg, 1889, p. 204-7).

sphere of molecular action was measured exactly. A number of physical problems were treated, with which in England Lord Kelvin, the late Prof. Clerk Maxwell, Prof. Reinold, Prof. Rücker, Lord Rayleigh, and others have also occupied themselves. The criticism therefore seems not justified.

I know very well that in Germany several representatives of the descriptive natural sciences do not agree with my views about the structure and the movement of protoplasm. For instance, Prof. Pfeffer[1] reproached me with "having, without deducing my views from admissible foundation on experience in organism, exclusively constructed them by physical experiments, and thereupon demanded, in an unwarranted manner, a peripheric oil-layer for protoplasm."

Here, too, let me remark, that I concluded the existence of this peripheric oil-layer from the globular form of the surface of protoplasm in plasmolysed cells and that I tried for months to find in living cells the characteristic periodic spreading, suspected by me, on the inner side of the hypothetical oil-layer. I have several times observed this spreading and the destruction of the globular form caused thereby. The observations of living cells have led me to fresh physical experiments, which I published in the year 1888, together with my theory of the structure and movement of protoplasm. These theories I have always found corroborated in the continuation of my researches since 1888. My adversaries, on the contrary, have as yet not given a satisfactory physical explanation for the above stated phenomena, the globular form of protoplasm surface and the movements in the vicinity thereof. Up to the present day I believe my views to be correct and irrefuted.

The facts observed and the physical conclusions inferred by me, may appear extraordinary and not very intelligible to another science, but they are none the less correct and useful. Biological science must, well or ill, take into account the fact that the development of the cell and the life of the organic nature depends on masses and layers which cannot be perceived by the microscope alone.

Heidelberg, October 22. GEORG QUINCKE.

Human and Comparative Anatomy at Oxford.

IN the article which appeared in your last number under the above heading, expressions occur which may, I think, lead to misconception as to the position of the department of Human Anatomy. It is of such importance in the interest of scientific medical education that the academical teaching of human anatomy should *not* consist merely in "technical training in anthropotomy," that I cannot allow the statement that the teaching of the subject in Oxford is of this nature to pass without comment. Had the writer of the article in question taken the trouble to inquire of the University lecturer here, or of any of the University professors of human anatomy elsewhere, for instance at Cambridge, Edinburgh or Dublin, or had he consulted any of the leading text-books of the subject, he would have found that its scope is much more extended than he supposes. The misstatement having been made, however unintentionally, must be corrected.

Let me add that the department, which was founded in 1885, was not connected in its origin with the department of Comparative Anatomy, and has had no relation whatever with it since. J. BURDON SANDERSON.

Asymmetrical Frequency Curves.

OWING to the haste with which I looked through the proof of my letter in last week's NATURE (p. 615) two slips escaped me, which I hasten now to correct. The ordinates in the diagram should have been marked $\frac{ap^n}{c}$, $\frac{anp^{n-1}q}{c}$, $\frac{an(n-1)p^{n-2}q^2}{1.2.c}$, &c., the factor $\frac{1}{c}$ having been dropped. Further, the value for c should have been

$$c = \frac{\sqrt{2(2\mu_2^2 - \mu_4)\mu_2 + 3\mu_3^2}}{\mu_2 a},$$

my a having been converted into a square power.

The method applied to Dr. Venn's curve fits it with an accuracy only surpassed by the generalised probability curve itself. KARL PEARSON.

University College, October 28.

Telegony.

As already stated in my previous letter, I have discussed this subject in my recently published "Examination of Weismannism" more fully than in NATURE. If "M. D. H." (NATURE, October 19) will consult the reference given in that letter to this work, he will find the facts to which he directs my attention are there given, together with certain reasons for concluding that they do not materially affect the point in question.

Hyères, October 26. GEORGE J. ROMANES.

AN ORNITHOLOGICAL RETROSPECT.

DURING the year 1892 there were at least three publications which are of great value to ornithologists, though from somewhat different points of view. They are Prof. St. George Mivart's little work on the "Elements of Ornithology,"[1] Dr. Gadow's "Classification of Birds," published in the Proceedings of the Zoological Society, and Capt. Bendire's "Life-Histories of North American Birds."

To thoroughly appreciate the value of Prof. Mivart's "Elements" one has to be the curator of a museum. Many people, like myself, must have been puzzled by the frequent demand for an elementary, but comprehensive book on birds, such as a man can carry with him on his travels, and many people about to journey abroad have asked me for a small book which would explain to them what certain birds were like. I prophesy that Prof. Mivart's book will make many collectors, and its handy size is one of its best features. There have been many introductory works on ornithology published in this country and America, notably those of Prof. Elliott Coues, but nearly all of them are too bulky, and that is the fault with the most popular works, such as the "Standard Natural History" and Cassell's "Popular Natural History." Commencing in an easy and unconstrained manner, Prof. Mivart in his Introduction leads his pupil on through the various forms of bird-life, his object being not to weight the tyro with too heavy material for study at starting. All the leading Avian types are passed in review and they are illustrated by some admirable woodcuts by Mr. Keulemans, drawn especially for the work. It is, therefore, possible for any one to understand what a particular form of bird is like, the only drawback to this mode of illustration being the impossibility of illustrating the subjects on the same scale, so that some of the smaller forms appear to be larger than they really are in comparison with the bigger birds. This was, however, unavoidable.

Three chapters (pp. 134–234) are devoted to the anatomy and osteology of birds, and a fifth chapter deals with their geological and geographical relations (pp. 235–250). That on the "Classification of Birds" summarises the chief characters for each order, suborder, and family, and lastly there is an enumeration of the genera with the number of species in each. This is of course mainly derived from the British Museum "Catalogue of Birds," and I find that on adding up Prof. Mivart's figures, the number of known species is 11,900. The last time that a computation of the number of birds was made was in 1871, when the late Mr. G. R. Gray finished his "Handlist of Birds," and admitted 11,162 species as then known. This was probably a correct estimate, as I have generally found that the "Handlist" contained about enough false species to counterbalance the number of species described since the work was issued. For similar reasons, Prof. Mivart's estimate of 12,000 species will turn out to be approximately correct, and then by adding the number of species described since his book was published, and others discovered since the issue of the "Catalogue of

[1] St. George Mivart, "Birds: The Elements of Ornithology." 8vo, pp. vi.-329 (London, 1892.)

Birds," we may fairly consider that about 12,500 species of birds are known to exist at the present day.

Dr. Gadow's "Classification of Birds" is based on very careful and exact study, and certainly carries this perplexing subject several steps further as regards the higher groups. There is now a good opportunity for any naturalist, working on the same exhaustive lines, to give us a classification of the Passeries, and it is to be hoped that Dr. Gadow will some day be induced to take up this study. In my address to the Ornithological Congress at Budapest in 1891, I advocated the employment of every external and internal anatomical character, as well as the nesting habits and the geographical distribution, for the achievement of a natural classification. Dr. Gadow has not only worked upon the same lines, but has further personally examined the anatomical features on which his classification is mainly based, and he has selected some forty characters, which he considers to be of essential value in determining the various orders and families. Dr. Shufeldt will doubtless not agree with the author's conclusions regarding the *Macrochires*, and it seems to me somewhat strange to find the Hornbills allowed no higher rank than as a sub-family of the *Upupidæ*, while the position of the *Striges* in the *Coraciformes* will doubtless excite a good deal of criticism. There can, however, be no question that the amount of work which Dr. Gadow has managed to compress into some five-and-twenty pages will be found to contain some highly original ideas, and such as must materially influence the mind of the next worker on the classification of birds.

The third work alluded to above is the "Special Bulletin" of the U.S. National Museum, a goodly 4to volume of 416 pages, with 12 coloured plates of eggs. The figures are beautifully rendered by chromolithography, and the publication is altogether a notable one. The letterpress is the work of Capt. Charles Bendire, who is known to be one of the most practised oologists of the present day. He has described and figured in the present volume the eggs of all the North American game-birds, pigeons, and birds of prey, and he has used his opportunity to the greatest advantage by giving an excellent account of the life-histories of the species, together with the latest information respecting their geographical distribution. Capt. Bendire's work forms one of the most important of the recent contributions to ornithological knowledge, and the succeeding volumes will be awaited with eagerness by ornithologists.

The issue of several good faunistic works on various parts of the British Islands, brings within measureable distance the time when it will be possible to take a detailed review of the ranges and occurrences of the birds which inhabit the above-mentioned area. Some of the books alluded to are of the lighter kind, like Dr. Hamilton's "Riverside Naturalist,"[1] and Mr. John Watson's "Poachers and Poaching,"[2] wherein the authors relate their own personal experiences of animal and plant life. In Dr. Hamilton's book the birds occupy nine chapters (pp. 21–165), and he gives a series of chatty and well-written notes, giving quite a full review of the birds which come under the notice of the fisherman or stroller on the river's bank. The book is a pleasant companion for a holiday outing, and it is a pity that the illustrations are not more up to the mark, for M. Robert's woodcuts are not worthy of insertion in any book which pretends to scientific accuracy, as they are evidently drawn from stuffed birds, and in some cases it is impossible to tell what they are meant for, the illustration of the "redbreast" on p. 105 being equally suggestive of a black redstart, while the sparrow-hawk's head on p. 153 is certainly that of a cuckoo!

Mr. Watson's collection of essays, gathered from several publications, is very good reading, and ranges over a wide field of subjects, with some of which "poaching" has nothing to do. As is inevitable in a series of articles contributed to different publications, the author travels over the same ground more than once in the course of the book, but the latter is always readable, and when Mr. Watson writes from his own first-hand experiences, he tells his story as a field naturalist should. In some of the remarks which he makes, however, we notice that he does not always acknowledge the source of his inspiration.

Some of the faunal works issued during the last year or two have been of special excellence, especially those published by Mr. David Douglas, of Edinburgh, which deal with the Zoology of Northern Britain. One of the most interesting of these is the "Birds of Iona and Mull," edited from the MSS. of the late H. D. Graham by Mr. J. A. Harvie-Brown. The work was originally edited by the late Robert Gray, the well-known author of the "Birds of the West of Scotland," whose appreciative preface is also given in the work; but he did not live to see its publication. The volume consists firstly of letters sent by Graham to Robert Gray, not only from Iona, but from his later home at Littlehampton, in Sussex, where his references to shooting at Pagham must kindle remembrances in a few of us who can still call to mind collecting in that fine old haunt of the naturalist. After some "extracts from diaries," a list of the birds of Iona and Mull is given. The book is enlivened throughout by sketches by the author, illustrating the wild country in which he lived, and the shooting experiences so well related in its pages. These little sketches are spirited and amusing enough, though sometimes the sportsman seems to be firing "in among the crowd" of his companions in the boat. From the usual position of the gun, the little dog—who was Graham's constant companion in his collecting-trips—must have had some narrow escapes, and perhaps that is why the last picture in the book represents the dog's tombstone.

Another of Mr. Douglas' excellent publications is the "Vertebrate Fauna of the Orkney Islands," by Mr. T. E. Buckley and Mr. J. A. Harvie-Brown. The birds occupy the bulk of the volume (pp. 91–264, app. pp. 297–302), and are treated in a very full manner, as might have been expected from the well-known reputation of the authors. The natural history of the Orkneys has been several times chronicled, the best-known works being those of the Rev. George Low, who wrote about 1770, and of Messrs. Baikie and Heddle, in 1848. The list of writings relating to the natural history of the islands, as given by Messrs. Buckley and Harvie-Brown, is considerable, and some excellent photographs of scenery are given, in addition to some spirited pictures of bird-life by Mr. J. G. Millais. The above-named authors have also published, in 1892, a "Vertebrate Fauna of Argyll and the Inner Hebrides," which forms a companion volume to the "Fauna of the Orkneys" and the other works on Scottish Natural History published by Mr. Douglas.

To Mr. R. H. Porter we are indebted for the publication of some very useful contributions to British Ornithology. In 1891 was published Mr. Borrer's "Birds of Sussex,"[1] with six beautiful coloured plates by Keulemans, illustrating the Gyrfalcon, the Honey Buzzard, the Rufous and Aquatic Warblers, the Nutcracker, and the Squacco Heron, all rare visitors to Sussex and the British Islands generally. Mr. Borrer is one of the old school of ornithologists, and has been an esteemed correspondent of

[1] "The Riverside Naturalist. Notes on the various forms of life met with either in, on, or by the water, or in its immediate vicinity," by E. Hamilton. 8vo. pp. i.-xviii. 1-401. (London, 1890.)

[2] "Poachers and Poaching," by John Watson. 8vo. pp. i.-viii. 1-326. (London, 1891.)

[1] "The Birds of Sussex." By William Borrer. 8vo, pp. xviii, 385, pls. i.-vi. with map. (London: R. H. Porter, 1891.)

all the well-known writers on British birds during the past fifty years, from Yarrell downwards. His notes range over a number of years, and, from his long experience as a collector, he has been able to write an exhaustive list of the birds of Sussex, on which he is undoubtedly the best living authority. Mr. Pidsley's "Birds of Devonshire"[1] is also a useful contribution to our local knowledge, and is accompanied by an excellent coloured figure of the Buff-backed Heron in breeding plumage, in which state, however, it does not appear to have been met with as yet in Devonshire. Mr. Pidsley's book, however, is eclipsed in size and importance by another work on the ornithology of the same county by Mr. D'Urban and the Rev. Murray A. Mathew.[2] Both these gentlemen have long been known as workers at the statistics of Devonshire birds, and the accounts of the species are very complete as regards their distribution in the county. A very good notion of the geography and natural features of the district is added, and some photographs of Lundy Island and other noted haunts of birds are given, as well as coloured plates, by Keulemans, of the Black Redstart, Montagu's Harrier, and a dark variety of the Rough-legged Buzzard, as well as the Great Black-backed Gull, which is one of the rarities contained in the Albert Memorial Museum at Exeter. It is a little curious that neither Mr. Pidsley nor the authors of the larger work on the "Birds of Devon" allude to the Montagu specimen of the Gull-billed Tern, which received its name of *Sterna Anglica* from the author of the Ornithological Dictionary. The specimen was taken in Sussex, and is still in the British Museum, having so far survived the decay which has overtaken a considerable portion of the Montagu collection. Several specimens from the latter no longer exist, having no doubt perished in the course of years, as none of them seem to have been properly preserved, and in most cases still have the bones of the trunk inside them. In addition to the list of the British-killed examples of the Gull-billed Tern in summer plumage, we may add to the enumeration given by Messrs. D'Urban and Mathew a beautiful bird in the British Museum from Christchurch, presented by Baron A. von Hügel.

Mr. D'Urban adds some tables showing the lines of migration of birds across Great Britain, opening up a new and fascinating branch of ornithological study to English readers.

The most recent addition to our local Avifaunæ is Mr. Whitlock's "Birds of Derbyshire,"[3] which is on the plan of similar works issued of late years, giving a county map and photographic illustrations of the most salient features of the district treated of. Derbyshire is a most interesting county, as it comprises within its area so many different kinds of country, each with varying characteristics. The notes on the migration of birds are good, as are also the accounts of the Ring Ouzel, Dipper, Pied Fly-catcher, and other birds which frequent the famous peak.

Amongst other books of interest to the student of British Ornithology may be mentioned a popular edition of the St. John classical work, "A Sportsman's and Naturalist's Tour in Sutherlandshire." Mr. Wintringham's "Key to the Classification of British Birds" is a small book, which gives tables of the orders, families, and species of birds inhabiting the British Islands; but it should have been called a "List" not a "Key," as there is not a single character given whereby a species may be distinguished. When a complete analysis has to be made of all the works which deal with British Ornithology, so as to illustrate by statistics the distribution of birds throughout Great Britain, Mr. Miller Christy's little "Catalogue of Local Lists of British Birds" will be found most useful.

A recent reviewer has stated in the columns of a leading London paper, that ornithologists are the only people to whom, in the present day, the "insulting character of Dr. Dryasdust is applicable," that they, as a body, take no interest in any problems connected with the past history or evolution of birds, "like Gallio, caring for nothing of these things, and, like Gallio, acquiring a considerable reputation by their attitude!" No wonder that, to this reviewer, the volumes of the British Museum "Catalogue of Birds" appear "most terrible publications." To understand the latter a man must be an ornithologist, which the writer of the above-quoted nonsense evidently is *not*. A direct contradiction to the sage declarations of the reviewer is given by glancing at the list of ornithological works of the year 1892, when it will be seen that in every branch of the subject considerable progress has been made, and that this country is by no means behind the rest of the world, either in the number or the quality of its productions. Lord Lilford has continued his beautiful coloured figures of British birds, a work now hastening to a successful issue, and accompanied by a series of short but entertaining notes, based upon the author's wide experience as a field naturalist in younger days. On the Continent, some of the results collected from the various stations of observation in the different countries, and summarised by Drs. Meyer and Helm, Dr. von Middenkorf, Mr. Winge, and others, are bound to form an important basis for reliable conclusions when a new history of European birds has to be written. One of the most complete of these summaries is to be found in Prof. Giglioli's third and concluding volume on the Italian orins.[1] In this volume Dr. Giglioli summarises the general results of the observations of the corps of auxiliary naturalists who have helped him with statistics, and the migrations of birds are treated of under various headings and according to localities, while the notes on nidification of Italian birds and their food are also classified, a copious index enabling the crowd of facts relating to each species to be easily found. Four parts of the large folio work on the birds of Italy were also published in 1892 by Dr. Giglioli, with coloured figures by Signor A. Manzella.

Dr. Pleske's great work on the ornithology of Russia is making progress, and considerable addition to our knowledge of the Avifauna of Thibet and Mongolia has been achieved by the Russian travellers Grum-Grzimailo and the expedition of Prince Henri of Orleans and M. Bonvalot.

In Ethiopian ornithology there are several interesting events to chronicle. Prof. Barboza du Bocage has published a supplement to his "Ornithologie d'Angola," embodying the results of recent exploration in that province, and bringing the work up to date. The collections made by Señor Francesco Newton, for the Lisbon Museum, in the island of St. Thomas, have also been described by Prof. Bocage, and some interesting new species discovered. The writer has finished the description of Mr. F. J. Jackson's collections, formed during the latter gentleman's journey to Uganda, and Mr. H. H. Johnston, C.B., has sent several consignments from Nyassa Land, where he has an experienced naturalist, Mr. Alexander White, working for him. The visit of the

1 "The Birds of Devonshire." By William E. H. Pidsley. Edited, with an introduction and short memoir of the late John Gatcombe, by W. A. Macpherson. 8vo, pp. xxx. 194, 1 plate and map. (London and Exeter, 1891.)

2 "The Birds of Devon." By W. S. M. D'Urban and Rev. Murray A. Mathew. With an introduction, and some remarks on the migrations of Devonshire birds. Pp. lxxxvii. 459. Plates i-ix. With three maps. (London: R. H. Porter, 1892.)

3 "The Birds of Derbyshire." By F. B. Whitlock. Annotated with numerous additions by A. S. Hutchinson. Pp. vi. 240. (London and Derby, 1893.)

1 Giglioli, E. H. "Primo Resoconto dei risultati della Inchiesta Ornitologia in Italia." Parte Terza ed. Ultima. "Notizie d'Indole Generale, Migrazioni, Nidificazione, Alimentazione, etc." 8vo, pp. vii. 518. (Firenze 1891.)

latter to the Milanji mountains resulted in the discovery of several new species, allied representatives of others inhabiting Kilimanjaro, Elgon, or even the Camaroon peaks. The collections made by Emin Pasha and Dr. Stuhlmann in Uganda resulted in the discovery of some interesting novelties, which have been described by Dr. Reichenow, at Berlin, who has also received some important collections from the Camaroons, from Dr. Preuss, and from Togoland. Mr. Johnston, at the present moment, appears to be the only patriotic Englishman who is taking pains to explore the natural history of the countries under his rule, whereas the Germans seem to have in every one of their "spheres of influence" and protectorates some well-informed naturalist who occupies himself with the natural history of the district.

The Indian region, formerly the scene of so much ornithological activity, seems, during the last few years, to have passed into a quiescent stage, and the principal work is now being done by Mr. Hose and Mr. Everett in Borneo, and Mr Styan in Southern China. Dr. Modigliani's collections, from the Island of Nias, were described last year by Count Salvadori, and showed that some of the species found by the traveller were akin to those of the Nicobars, while, curiously enough, others were allies of Bornean forms rather than Sumatran, though the latter affinity would have been expected. The death of Mr. Davison, at Singapore, has deprived us of one of the best-known Indian naturalists. His explorations in Tenasserim gained him immortal fame as a collector, and, had his health been stronger, he would no doubt have continued his researches into the natural history of the Malay Peninsula, where much still remains to be done. His last expedition to Pahang resulted in the discovery of a very fine new starling (*Æthiopsar torquatus*).

Dr. A. B. Meyer, who has identified himself with the pursuit of Natural History in New Guinea and the Moluccas for many years, has received some collections from Kaiser Wilhelm's Land in north-eastern Papua, wherein have been some interesting new species, while in the southern portion of the great island Sir William McGregor has discovered some extraordinary new forms of birds, one of which, *Paramythia*, is such a puzzle that no one has been able to define its place in the natural system with any confidence. The completion of Count Salvadori's "Uccelli di Papuasia e delle Molucche" marks an epoch in the history of Austro-Malayan ornithology, and this wonderful work with its appendices will remain for ever a monument to its painstaking and accomplished author.

In Australia the most notable work of recent years has been Mr. A. J. North's description of the nests and eggs of the birds inhabiting that continent.[1] This book not only contains a vast amount of additional material on the nesting-habits of Australian birds, but is accompanied by photographic illustrations of the eggs, while a few coloured copies have been prepared, one of which has been sent to the Natural History Museum. An appendix describes the nests and eggs of the birds inhabiting Lord Howe and Norfolk Island.

In New Zealand Sir Walter Buller has been assiduously collecting additional notes to supplement his recently completed work on the birds of that country, and Prof. Hutton has given some notes on the Moas, which will have to be critically compared with Mr. Lydekker's recent determinations of these struthious birds. By far the most interesting event, however, of recent years has been the discovery by Mr. H. O. Forbes, the celebrated Malayan traveller, of the remains of *Aphanapteryx* in the Chatham Islands. *Aphanapteryx* was previously known only as a former inhabitant of the Island of Mauritius, and the discovery of identical remains in a locality so far distant as the Chatham Islands, has opened up possibilities of speculation of the most intense interest, and Mr. Forbes' recently exploited theory of the former existence of a great Antarctic continent has changed the ideas of many zoologists with regard to the origin and geographical distribution of many forms of animals and plants. It is decidedly the most interesting episode of the year 1892.

Polynesian ornithology has undoubtedly been forcibly brought before our notice by the careful work which has been done by Mr. Wiglesworth, in his "Aves Polynesiæ," and a complete list of the species inhabiting the Pacific Islands, with their synonymy and geographical distribution, has been published in the "Abhundlungen" of the Dresden Museum, under Dr. A. B. Meyer's care. Mr. Scott Wilson, with the help of Mr. Evans, has reached the fourth part of the "Aves Hawaienses,"[1] and with one more part the work will be brought to a conclusion. Mr. Wilson gives some interesting notes on the habits of the species, but it is doubtful whether he has obtained all the material necessary for a monograph of the Hawaian Avifauna, judging by the number of new species which the Hon. Walter Rothschild has been receiving from his collector, Mr. Palmer. These may, of course, be included in the final part of the work, thus bringing it up to date. A visible improvement is to be noticed in the plates of Mr. Frohawk, and the coloured figures of the species look something like the actual birds, instead of being a sort of map, as heretofore.

Except for the splendid paper by Dr. Gadow, before mentioned, on the classification of birds, very little anatomical work has scarcely been done, in England at least; and it is to be hoped that Mr. Beddard, who has before now written some useful ornithological papers, and on whom the mantle of Garrod and Forbes is supposed to have fallen, will give us some further results from the splendid opportunities which he enjoys as prosector at the Zoological Gardens.

R. BOWDLER SHARPE.

HENRY OLDENBURG, FIRST SECRETARY OF THE ROYAL SOCIETY.

"SIR, you will please to remember that we have taken to taske the whole Vniverse, and that we were obliged to doe so by the nature of our Dessein. It will therefore be requisite that we purchase and entertain a commerce in all parts of ye world wth the most philosophicall and curious persons, to be found everywhere." So writes Henry Oldenburg to Governor Winthrop of Connecticut on October 13, 1667. And in these words he briefly expresses what was the chief aim of the best years of his life. It was mainly by his immense correspondence that Oldenburg forwarded the cause of science, or, as it was then called, of the "new experimentall learning," by that and by his assiduous discharge of secretarial and editorial work. Without being a man of brilliant genius, he was just such an intelligent, reliable, energetic, and conscientious worker as was needed at that time to form a centre for the new movement. In the history of literature Henry Oldenburg is a familiar figure as the friend and correspondent of Milton; in the history of philosophy, as the friend and correspondent of Spinoza; but neither literature nor philosophy is indebted to him to the same extent as science.

It is somewhat remarkable that, although the name of Henry Oldenburg is so familiar in the history of the seventeenth century, no complete life of him has ever been written. The only attempt at a con-

[1] Scott B. Wilson, assisted by A. H. Evans. "Aves Hawaienses: the Birds of the Sandwich Islands." Parts iii. iv. 4to. (London: R. W Porter, 1892, 1893).

nected biography is that of Dr. Althaus, of University College, London, who, in 1888, contributed to the *Allgemeine Zeitung*, published in Munich, a series of very interesting articles upon the life and correspondence of this remarkable man. These he supplemented at a later date by many new facts as to Oldenburg's birth, parentage, education, and early life, the results of researches undertaken at his instance by Dr. von Bippen, Archivist of Bremen. Until these facts were published by Dr. Althaus, we knew nothing whatever of Oldenburg's early life. He appears suddenly upon the scene as the agent for Bremen with the English Commonwealth and a correspondent of Milton's, but who this friend of Milton's was, and from what pit he was digged, no one seems to have taken much trouble to inquire.

We did not, as it now turns out, know so much as the date of his birth, for it is evident from Dr. von Bippen's researches that the date 1626 usually given in biographical dictionaries as the date of Oldenburg's birth is altogether wrong, and that as a matter of fact he must have been born about 1615, a date which puts the whole of his life and correspondence in an entirely new perspective. He was, according to this, only seven years Milton's junior, which accords much better with the tone of their correspondence, and he was seventeen years older than Spinoza, which perhaps partly accounts for the somewhat fatherly manner in which he encouraged that philosopher to publish certain of his works. Equally at sea are the biographical dictionaries (and other works too) as to his descent. The statement copied from book to book that he was descended from the Counts of Oldenburg appears to have been a pure "shot," inferred partly from his name, and partly from the fact that in his matriculation entry at Oxford he is called "nobilis Saxo," which means nothing at all. What we do now know about him is that he was the son of Heinrich Oldenburg (d. 1634), a tutor in the Gymnasium at Bremen, the grandson of another Heinrich Oldenburg (d. 1603), Professor of Mathematics in the same Gymnasium, and great-grandson of Johann Oldenburg, who came from Münster in 1528 to be the first rector of the Evangelical school at Bremen; and that he was one of a large family who lived in somewhat narrow circumstances.

As to Oldenburg's education, we learn that he studied first at the Evangelical school and afterwards at the Gymnasium illustre in Bremen, and that on November 2, 1639, he took there the degree of Master in Theology, the subject of his thesis being "De ministerio ecclesiastico et magistratu politico." Whether, like Gotthold Lessing at a later day, he was intended by his parents for a theologian, we do not know. He did not break with theology so completely as Lessing did, for throughout his life there was a certain theological flavour about him, and, in his interesting "commonplace book" preserved among the archives of the Royal Society, there is an entry of fifteen pages headed "Sensa Animi mei de Deo et ejus cultu naturali"; but he revolted from the *à priori* methods of the current teaching, and in the same MS. we find accordingly many vigorous passages directed against "the vain shadows of scholastic theology and nominalist philosophy." These outbursts, however, belong to a later date. It was as a theologian that he graduated at Bremen, and then, for some unknown reason, he went to England.

In England he lived for eight years, probably in the capacity of a tutor, probably, too, in royalist families. Some evidence, at any rate, exists in the Bremen archives that during this first English residence he took the king's side against the Parliament. Then comes a gap of four years, during which there are hints that he was travelling upon the continent of Europe and cultivating those numerous acquaintances with learned men, which afterwards stood him in such good stead when his life-work was to gather scientific information from all parts of the world.

From June, 1653, however, his life becomes clear. In that month he was, as I have said, appointed agent for Bremen, in which capacity he had audiences with Cromwell, and made the acquaintance of Cromwell's Latin secretary, John Milton. The acquaintanceship ripened into friendship, and an elegant but somewhat ponderous Latin correspondence followed. Oldenburg's political mission came to nothing, and then we find him in a country village in Kent waiting in uncertainty as to public events and as to his own future career. That career was, however, very soon determined, for in 1656 he went to Oxford, and was immediately caught in that current of "experimental learning" which had already begun to flow. Boyle, Wilkins, Wallis, Petty were his constant associates, and his letters at this time show the strong scientific impulse which his mind had received.

The passage in Anthony à Wood's "Fasti Oxonienses," which records Oldenburg's Oxford residence, is as follows:—"1656. In the beginning of this year studied in Ox. in the condition of a sojourner Henry Oldenburg, who wrote himself sometimes Grubendole, and in the month of June he was entred a student by the name and title of Henricus Oldenburg, Bremensis, noblis Saxo; at which time he was tutor to a young Irish nobleman called Henry ô Bryen, then a student also there." Besides Henry O'Brien he had another young nobleman as his pupil during his Oxford residence, namely Richard Jones, son of Catherine Lady Ranelagh and nephew to the Hon. Robert Boyle, and after remaining at Oxford for about eighteen months he accompanied young Ranelagh upon a journey to the Continent. For a year they remained at Saumur, and while there letters continued to pass between him and Milton. It is rather amusing to read that Milton had entrusted to Oldenburg a packet of his latest politico-theological writings for distribution to foreign savants, a task which the cautious Oldenburg did not half like, and which he executed, as he informed Milton, by giving copies of the writings "to no one who did not ask for them." How many asked for them he does not say. It was not in truth with the fierce political and theological controversies of the time that Oldenburg's mind was now engaged. He had gained a new interest and was travelling with a new object. His scientific observations were certainly very mixed, many of them trivial, and some of them superstitious, but they serve to show the direction in which his mind was travelling. From Saumur he sends to Boyle "noteworthy observations concerning the existence and the working of animal poison," and a chemical recipe for an invisible ink, and says that if his travels take him to Italy it will be a satisfaction to give Boyle "news of the industrious Kircher's subterraneous world, his strange Grotta de' Serpi, his story of the growth of pulverised and sowne cockles irrigated by sea-water, his thermometre by a wild-oats-beard, his vegetable phœnix's resurrection out of its owne dust by y^e^ warmth of y^e^ sun, his pretended ocular confutation o^f^ Kepler's magnetical motions of y^e^ Planets about the Sun, and of Gilbert's magneticall motion of y^e^ Earth and of twenty other remarquable things."

At a later date he sends Boyle from Paris the recipe of a wonderful oil which he had picked up in the course of his travels, which was supposed to heal "migraines, palsies, lamenesses, crookednesses, and all ricketing diseases." More wonderful even than this wonderful oil is another of his discoveries, for Samuel Hartlib, in a letter dated April, 1659, informs Boyle that Oldenburg has written to him from Paris that he has in that city discovered a "clever, but very secretly acting" physician, who had spoken to him of a method by means of which one can prepare a drink from sunbeams!

Meanwhile Boyle and the other Oxford worthies con-

tinued their pursuit of the "new philosophy," meeting generally at that time in "Dr. Wilkins's lodgings in Wadham College." The London branch of the same movement, too, was now becoming active, meeting usually at Gresham College "at the Wednesday's and Thursday's lectures of Dr. Wren and Mr. Rorke." After the Restoration many of the Oxford professors lost their positions and came to London, and on the 28th November, 1660, at the close of a lecture of Wren's at Gresham College, it was resolved to reconstitute the Society, which had hitherto been somewhat amorphous, as a "Society for promoting the physical-mathematical experimental sciences." Oldenburg, who had just returned from abroad, was elected a member of the first Council, and he and Dr. Wilkins were chosen the first secretaries of the Society. From that moment Oldenburg threw himself heart and soul into the work of the Society. Its interests he regarded as his own, and Prof. Masson gives it as his opinion, and with justice, that without his endeavours and those of Hooke, the Society would scarcely have held together. The great difficulty, of course, was the want of money. Charles II., the so-called "Founder," had promised to endow it, but he broke his promise and only gave it a mace. The Society could not afford to pay its secretary, and yet the secretary must live. In the British Museum is preserved a rough memorandum in Oldenburg's handwriting, quoted, but not very accurately, by Weld in his "History of the Royal Society," which gives a very vivid idea of the secretary's labours and poverty. It runs as follows:—

The Business of the Secretary of ye R. Soc.

He attends constantly the meetings both of ye Society and Councill; noteth the observables, said and done there; digesteth y^m^ in private; takes care to have y^m^ entered in the Journal and Register-books; reads over and corrects all entrys; sollicites the performances of taskes recommended and undertaken; writes all Letters abroad and answers the returns made to y^m^, entertaining a corresp. w^th^ at least 30 psons; employes a great deal of time, and takes much pains in satisfying forran demands about philosophicall matters; disperseth farr and near store of directions and inquiries for the Society's purpose, and sees them well recommended, etc.

Qy. Whether such a person ought to be left vn-assisted?

In connection with this may be mentioned another memorandum of Oldenburg's. It is preserved in the same MSS. (Birch MSS. 4441), and is headed as follows:—

Liste of Members yt are likely to promote ye dessein of ye R. S.

Members yt will probably both pay and give yearly one entertainment to ye Society.	Such, as will pay, and procure an entertainment to be made by others.

In the first column occur among others the names of Boyle, Petty, Wren, Evelyn, Wallis, Croon, Grew, Pell, Mercator, Hook, Collins, Newton, and Smethwick. Against the names of Newton, Grew, Pell, Mercator, Hook, Collins, and Smethwick are written the words "no pay."

The "no pay" element was one main difficulty of the new Society. Even those who promised to pay, frequently neglected to do so. In 1666 the arrears amounted to £600 sterling, and in 1673 to £1957, and this, notwithstanding strenuous efforts on the part of the Secretary to collect the contributions. In fact, at that time, out of 156 Fellows, only 53 paid regularly.

At the beginning of 1664 Oldenburg was authorised to make what he could by publishing the Transactions of the Society, but they were printed at his own risk, and seldom brought him in as much as £40 a year. The very next year the Plague appeared in London and drove away the book-purchasers, and the year after occurred the Great Fire of London, which ruined the booksellers, and made publication still more difficult. Besides all this, the sale of the Latin edition in foreign countries was greatly hindered by the war with Holland. And to crown all, in 1667, the very year after these great disasters, Oldenburg himself, who had stuck to his post through Plague and Fire, was imprisoned in the Tower of London. The warrant, which is signed by the Prime Minister, Lord Arlington, charges him with "dangerous plans and practices"; but the fact appears to be that the immense number of his foreign letters had attracted attention, and since the Government of that time did not understand a man who had, as he wrote in the letter quoted above, "taken to taske the whole Vniverse," this voluminous correspondence excited suspicion. He was kept in prison for two months, "during which comitment," as he afterwards wrote to Boyle, he "learned to know his reall friends." Among these friends was Evelyn, who visited him in the Tower on August 8. After his discharge he waited upon Lord Arlington, and then went down into the country to recruit. "I was so stifled by the prison-air," he writes on September 3, "that, as soon as I had my enlargement from the Tower, I widen'd it, and took it from London into the country, to fann myself for some days in the good air of Craford in Kent. Being now returned, and having recovered my stomack, which I had in a manner quite lost, I intend, if God will, to fall to my old trade, if I have any support to follow it."

He fell to his old trade with his old energy, and how indispensable that energy was to the Royal Society is shown by the fact that during his imprisonment the Society did not meet. Besides his purely official work and his voluminous scientific correspondence, he was ready at all times to do battle for the Society. For in those early days it was far from being plain sailing. The Society had to meet much odium, especially on the score that it was "an enemy of the established religion and destroyer of the ancient well-grounded learning"; and it is with reference to these charges that Oldenburg breaks out in the fifth volume of the *Philosophical Transactions*: "Let envy snarle, it cannot stop the wheels of Active Philosophy, in no part of the known world. Not in France, either in Paris, or at Caen. Not in Italy, either in Rome, Naples, Milan, Florence, Venice, Bononia, or Padua. In none of the Universities, either in this or that side of the seas. Madrid and Lisbon, all the best spirits in Spain and Portugal, and the spacious and remote dominions to them belonging; the Imperial Court, and the Princes of Germany; the Northern Kings and their best luminaries; and even the frozen Muscovite and Russian have all taken the Operative ferment, and it works high, and prevails every way, to the encouragement of all sincere Lovers of Knowledg and Virtue."

Oldenburg died suddenly in September, 1677, at Charlton, in Kent. In the Archives of the Royal Society there are no less than 405 of his autograph letters and drafts, besides ninety-four letters to Robert Boyle in a separate guard-book, and many rough drafts in his own private Liber Epistolaris. One letter in this last-named MS. book, which has not hitherto been published, I cannot forbear to mention in concluding this article, since it shows Oldenburg, even at that early date, as an advocate of the higher education of women. The letter is written to Lady Frances Jones, and is dated August 28, 1660. "I wish heartily," he writes, "that that sexe, which is thus advantaged by Nature with a choyce structure of body, and thereby gives cause to conclude, that the guest thereof must be more than ordinary, would not suffer themselves to be diverted from those nobler improvements they are, to speak the truth, as capable of as men; nor be contented to have their innate capacity in their education stifled or debased to the needle or the making of sweet meats." Many such passages, full of sound sense, might be quoted from his letters did the limits of this article permit, but at present we can only express a

hope that an interesting man who lived in a most interesting period may yet find a biographer who will adequately bring him into the light out of the shadow of the giants who were in the earth in those days—Cromwell, Milton, Newton, Spinoza, Boyle—in the midst of whom he moved, and by whose great names his own has hitherto been too much obscured. HERBERT RIX.

THE NATURAL HISTORY OF EAST EQUATORIAL AFRICA.

THE geology of East Equatorial Africa has been recorded in a very general way in the maps of the region published by Mr. Jos. Thomson in his "Through Masai Land," and in the more recent one of Prof. Toula; from these it was known that the area consists of a basal plateau of gneiss and schists, covered by a series of lavas in the interior and marked along the coast by patches of Jurassic rocks. My work therefore lay in the main in the examination of the gneisses and schists with a view to the determination of the method of their formation; also to the study of the volcanic rocks—which range from basalts to quartz trachytes—and of the relations of the old lava plateaus and sheets to the craters of various ages which play such a striking part in the scenery of the district. The most interesting part of the work consisted in the examination of the great "Graben" or valley of subsidence which runs north and south across the district; on the floor and on the sides of this are many old lake deposits now buried by lava flows, while the walls are also marked by terraces formed by the existing lakes when at a higher level than at present, or by old ones that have long since disappeared. In some of these terraces are shells with Nilotic affinities, though the localities are now far from the Nile basin. The collections made from the coast Jurassics will allow the age of these beds to be definitely settled, and the fossils—*Ammonites*, *Lytoceras*, *Belemnites*, &c.—suggest that they are probably Callovian. An interesting addition to the geology of tropical Africa has been the discovery of some Palæozoic shales, more than 130 miles from Mombasa, which have yielded a fairly good fauna, though richer in individuals than species.

The evidence collected proves the existence of a former race of men who used obsidian implements, and who lived in a period long prior to any existing tribes; and also, that the glaciers on Mount Kenia once extended several thousand feet further down the mountain than at present; in fact, a regular sheet or cap glaciation preceded the existing valley glaciation.

Zöologically the district is somewhat barren, and in many parts only animals with great powers of migration or hybernation are to be seen. In some of the country most famous for its game, none can be found, as it was killed off by last year's drought Cattle disease is responsible for the disappearance of many species; thus, whereas buffalo used to be extremely common, only three were seen; only one herd of giraffes was met with. Zebra and ostriches are abundant in places, while the commonest antelopes seen were the hartebeest, mpalla, and water-buck; topi are numerous on the Tana. The sparseness of dense forest, except on the higher parts of the district, accounts for the rarity of monkeys. *Colobus guerazi* was seen at over 9000 feet on Kenia, and some baboons amid the rocks of one of the ridges of the basin of Lake Kibibi. Hyena and a small bush buck range up into the lower Alpine zones on Kenia, while a small rat, Hyrax, and elephants occur in the woods of *Senecio johnstoni* in the upper Alpine zone. Another high record is the occurrence of fresh water crabs (*Telephusa*) in some swamps on Leikipia at the height of about 8000 feet.

The rarity of limestones doubtless helps to the scarceness of mollusca. As is well known, most of the species live on trees, whether in river valleys, such as the Sabaki, or among the forests of Kenia, where some small delicate species are common from 8000 to 10,000 feet.

Botanically also, the country is somewhat barren and monotonous; vast areas are covered by nothing but low, umbrella-shaped acacias. The country may be roughly divided into seven zones. The first includes the coastal plain and river valleys, characterised by the abundance of palms, such as the Dum palm (*Hyphœne thebaica*) and the Borassus palm (*B. flabelliformis*); the former is abundant along the coast and fringes the rivers, being found up the Tana as far as south of Kenia, and up the Sabaki to Tzavo. The Screw palm (*Pandanus*) is rarer, but has a similar range. The salt marshes and lagoons are bordered by the mangrove, while the she-oak, or *Casuarina*, occurs on the ends of exposed promontories on the coast. These have doubtless grown from cones carried by currents from Australia, just as the Krakatão pumice, which now forms banks along the shore, has floated from Malaysia. This zone is succeeded by great sandy steppes covered with mimosa and acacia scrub, with large baobabs, which occur also on the coast. The most typical plants have large and white flowers, a species of *Convolvulus* being the commonest Aloes, and especially the species known to the Suahili as "nkonge," are abundant. The two next zones are the steppes and woods of the high plateaus; the most striking feature of the former is the high grass, which, when the seeds are ripe and yellow, reminds one of the great cornfields of Dakota.

In places the forests of the plateaus pass upward gradually into those of the flanks of the higher mountains, such as Kenia and Settima. The prevalence of lofty junipers which replace the trees of lower horizons, and the dense jungles of bamboos, with a carpet of *Selaginella* characterise the fifth or bamboo zone.

Above this are the Alpine pasturages. In the lower part there are numerous orchids, *Gladiolus*, &c. With the upper zone there appear species of the "everlasting plants" of the Cape, while the only trees are *Senecio johnstoni*. Beyond this is the zone above the snow line, where except for a few diminutive yellow composites and lichens, we have passed beyond the realms of plant or animal life. J. W. GREGORY.

NOTES.

DR. POTAIN has been elected a member of the Paris Academy of Sciences (Section of Medicine and Surgery), in the place of the late Prof. Charcot.

WE are sorry to learn of the death of Dr. H. H. Ashdown, on October 10, at the age of thirty-four. He was a Fellow of the Royal Society of Edinburgh, and published several memoirs on his physiological investigations.

WE regret to announce that Mr. T. C. Bain, the Government surveyor and geologist at the Cape, died at Rondebosch, Cape Town, on September 28. He was born in 1830, and his father was the engineer of the well-known Mitchell's Pass Road, at Cape Colony. Mr. Bain was appointed irrigation and geological surveyor in 1888. The British (Natural History) and Cape Museums contain a number of geological specimens collected by him, among which may be mentioned the collection of reptilian remains from the lacustrine beds of the Karoo.

A STATE MUSEUM is now in course of formation at Pretoria. Mr. P. Krantz has been appointed a curator, and he has, with an entomological assistant, just started on a collecting expedition, which may probably occupy a space of two years. Their mode of transit is in a large wagon drawn by twenty donkeys, these animals having been chosen as best able to withstand the

vicissitudes of climate and attacks of "fly" pertaining to some parts of the country proposed to be visited. This wagon has been fitted inside and outside with shelves and other paraphernalia for holding specimens, cork, medicaments, &c. When not travelling, accommodation is found in a large marquee fixed to the side of the wagon, from which step-ladders, dissecting-tables, &c., may be let down. A lighter and rougher wagon, suited to more inaccessible country, also accompanies the party. Everything has been done to favour the success of this expedition, and the Raad has passed a resolution specially exempting those engaged in it from the provisions of the game law. The nucleus of a good general collection should thus surely be obtained, whilst the idea of collecting the Transvaal fauna is highly to be commended.

AN appeal for subscriptions to found a Pasteur Institute for India is about to be made (says the Allahabad *Pioneer*). It is proposed to locate the institution in some convenient place near Simla. There the necessary laboratories, fitted with the best scientific appliances, quarters for the officials, and accommodation for patients will be provided. The expenses will be very considerable, but the Government of India, besides giving their cordial approval to the scheme, have contributed notable help by promising the services of a selected medical officer. India has hitherto taken very little interest in bacteriological work, though almost every European nation, America, and Japan are devoting a large amount of attention to it. It is hoped that in addition to its anti-rabic work, the Indian institute may be put on such a footing as to enable it to carry on original research in this and other directions. The institute should also serve as a training school in practical bacteriology for medical men in India. The scheme is full of promise, and there should be little difficulty in obtaining the funds necessary to carry it out.

AT the Institution of Electrical Engineers, on Thursday, November 9, Prof. George Forbes, F.R.S., will read a paper on "The Electrical Distribution of Power."

ACCORDING to the *Pretoria Press*, and from a Blantyre source, a very large supply of ivory has come down from the Lake, in the Lake Company's possession. Huge 6 feet and even 7 feet tusks were to be seen at Mandala, and several thousand pounds must have been paid the Arabs in exchange for this valuable commodity.

AN International Horticultural Society was founded at the recent congress of horticulturists held at Chicago. The chief object of the society is to facilitate the exchange of plants, seeds, books, &c. The following officers have been nominated :—President, P. J. Berchmans ; Vice-President, Henry L. de Vilmorin ; Secretary and Treasurer, Mr. George Nicholson, the Curator of Kew Gardens. We are informed, however, that Mr. Nicholson is unable to undertake the work that this office would impose upon him.

AN International Exhibition of Industry, Science, and Art will be opened at Hobart, Tasmania, on November, 1894, and will continue open for a period of about six months. The exhibits will be arranged into twenty-four classes. Class X. is Chemistry, Apparatus and Processes, Philosophical Instruments; XI. is devoted to Electricity ; Gas and Lighting, other than Electricity, is the subject of Class XII. The following classes are also of scientific interest : XVI.—Machinery, Machine Tools, Hydraulic Machines, and Machines for raising heavy weights, Elements of Machines, Furnaces ; XVII.—Prime Movers, and means of distributing their power, Railway plant ; XVIII.—Naval Architecture and Engineering ; XIX.—Civil Engineering, Construction, and Architecture, Sanitary Appliances, Aeronautics, &c. ; XX.—Mining and Metallurgy, Minerals, Quarrying, and Fuel ; XXI.—Agriculture, Horticulture, Arboriculture ; XXII.—Fisheries.

A CORRESPONDENT writes : "There seems still little recorded as to the maximum or average size of the flying fish, *Exocœtus* sp. On my voyage to the Cape, on board the R.M.S. *Drummond Castle*, in about the longitude of Greenwich and the latitude 11° S., and on September 9 last, a specimen flew, or was blown, on board, where the bulwarks were 19 feet to 20 feet above the water, which measured $18\frac{3}{4}$ inches long, with an expanse of $22\frac{1}{2}$ inches across the wings. This was the largest specimen that has ever passed through my hands. It only weighed 1 lb. 6 oz., but a development in weight would clearly be disadvantageous to its power of flight."

IN the notice of Prof. Sylvester's life which appeared in NATURE for January 1889 (vol. xxxix. p. 217), it is mentioned that after coming out at Cambridge as Second Wrangler, "he was incapacitated by the fact of his Jewish origin from taking his degree," and it is added that in "more enlightened times (1872) he had the degrees of B.A. and M.A. by accumulation conferred upon him." The learned librarian of Trinity College, Dublin, Rev. Dr. Abbott, calls our attention to the fact, which should not be overlooked, that though unable to take the degree at Cambridge, he actually passed *ad eundem* to Dublin University, and had the degrees of B.A. and M.A. conferred upon him there (in virtue of his Cambridge qualification) in 1841. The honorary degree of LL.D. was also conferred upon him by Dublin in 1865. It may not be without interest to mention that the first Jew to obtain a degree in the United Kingdom was Nathan Lazarus Benmohel, who graduated B.A. at Dublin in 1836, and M.A. in 1846.

SIX years ago Hofrath Dr. A. B. Meyer, Director of the Natural History Museum at Dresden, published in the *Abhandlungen und Berichte des K. Zool. Museum Zu Dresden*, a series of descriptions and drawings of iron-framed cases, and of other museum fittings and apparatus introduced by him in Dresden. Since then a good deal of attention has been directed to the subject of metal instead of wooden framing in museum cases ; and in 1891 Dr. Meyer gave further details as to his experience in a communication to the Museums Association meeting at Cambridge. In the *Abhandlungen* of the Dresden Museum for the year 1892-3, just published, Dr. Meyer returns to the subject of iron-framed cases, on the details of which his recent experience has suggested several improvements. In a series of twenty lithographic and photographic plates, accompanied by elaborate specifications, measurements, &c., he deals with several forms of case, with store cabinets and their fittings, with trays for eggs and nests, sheet iron trays for shells, supports for skeletons and crania, craniometers, and several other varieties of museum appliance and case fittings. In truth Dr. Meyer has, with real German patience and industry, drawn and described in an exhaustive manner a range of museum cases and appliances which every curator more or less works out for himself, and of which, having by rule-of-thumb or otherwise attained his object, he thinks no more. But, as Dr. Meyer points out, museum officials are much given to experimenting at a loss of both time and money, and there is no reason why the results of well-matured experience should not be authoritatively laid down and generally accepted as a basis from which to reach forward to further improvements. The only other means than publication by which museum officials can obtain the results of mutual experiments and experiences is by visits to museums, but by that means alone the observer cannot get the precision of information and the working details which are conveyed by Dr. Meyer's monograph. The publication indeed confers a signal benefit on all interested in museum work, and it is much to be desired that

others having like valuable experience should follow Dr. Meyer's example, and put down with precision what they know and have accomplished for the benefit of the ordinary museum officer.

DR. KARL DOVE, in a letter addressed to the President of the Berlin Gesellschaft für Erdkunde, gives some interesting particulars regarding the climate and vegetation of South Damaraland. The numerous larger rivers, or rather water-courses, of the country contain water almost throughout the year, which in the dry season, however, is found underneath the superficial layer of sand. In August of last year Dr. Dove even found a strongly flowing brook, about ten feet broad, in the hot and dry valley of the lower Swakop. He attributes the permanence of the rivers to the profusion of strong inclines and the scarcity of purely horizontal plains, which has the effect of diminishing evaporation. The great efficiency of the protection afforded by the soil even in that dry country is shown by the fact that in places where moisture could only be due to rain, traces of it were found in samples at the depth of three feet after five months of the dry season. The amount of atmospheric precipitation was abnormally large during the last rainy season, and the sky was clouded very much like a north European rainy sky. During January over 11·8 inches were recorded in the vicinity of the higher mountains of Windhoek and the Sheep River. At Windhoek itself the mean rainfall is estimated at 15·8 inches. The discovery that the rainfall does not show a further increase from lat. S. 22° to 19° is of special importance.

AT a recent meeting of the British Ornithologists' Club, the Hon. Walter Rothschild read some notes on the genus Apteryx, and exhibited a very extraordinary number of living specimens of these "wingless" birds of New Zealand. He recognises the following as a complete list of the species at present known:—*A. australis*, Shaw, from the South Island; *A. lawryi*,* sp. nov. from Stewart Island; *A. mantelli*,* Bartl. from North Island; *A. oweni*,* Gould, the east coast, South Island; *A. oweni occidentalis*,* sub-sp. n., the North Island, and west coast, South Island; *A. haasti*,* Potts, central South Island and west of the North Island; and *A. maximus*, Verr. (sp. dub.), South Island. Males and females of those marked with an asterisk were exhibited, and also a female specimen of the new sub-species. Mr. Rothschild is engaged on a monograph of these strange birds.

DURING the construction of the Puy-de-Dome Observatory in 1872, the ruins of a large temple were discovered (says M. Plumandon in *La Nature*). From a tablet bearing a well-preserved inscription it appeared that the temple was consecrated to Mercury, and, according to historians, it was destroyed towards the end of the third century. Near the middle of the ruins of the temple, in the part that was originally the most highly decorated, there stands a small vertical wall, about one and a half yards high and rather more than two yards long, built of rectangular blocks of stone four inches high and about six inches in length. The blocks are of two different colours, one kind being of light dolomite, while the other is a black lava. The two colours are alternated in each horizontal row, and the rows are arranged so that the vertical joint between any two blocks falls at the middle points of the blocks above and below it. Proceeding, therefore, from the bottom to the top of the wall, or *vice versa*, the faces of the blocks of each colour form a zigzag pattern of which the lines are inclined about 60° to the horizontal lines separating the successive layers of stone. In fact, the mosaic constitutes a system of parallel lines cut by oblique lines of precisely the same kind as that which is frequently figured in illustration of optical illusions. When the wall is viewed from a short distance the horizontal layers seem to lose their parallelism, and appear to converge towards the interior of the angles formed by two consecutive series of obliques. Zöllner first called attention to the apparent loss of parallelism which truly parallel lines undergo when they are cut by oblique lines, but it is possible that the mosaic was designedly constructed to deceive the eye, and played an important part in the ceremonial of the temple on the Puy-de-Dome one thousand seven hundred years ago. *Nihil novum sub sole.*

MR. E. A. ANDREWS describes in the last (October) number of the *Studies from the Biological Laboratory of the Johns Hopkins University* an undescribed Acraniate, *Asymmetron lucayanum*, found in considerable numbers between North and South Bemini, Bahamas, in June and July 1892. They were taken in the tow-net while swimming at or near the surface, most abundantly at the early part of the ebb-tide when it had been high tide about nine o'clock in the evening, rarely in the day-time, or late at night, or on the rising tide. They were also obtained buried in the sand flats, but not very abundantly. The specimens taken in June were larger, often sexually mature, while those taken later were generally immature or larval forms. In captivity their habits were like the European lancelet, the largest was 16 mm. in length and sufficiently translucent to enable one to trace the food or carmine granules to be traced through most of the digestive tracts. The peculiarities of this form, and those which induced the author to venture to refer it to a new genus, are briefly: the gonads being present only on the right, instead of on both sides as in Branchiostoma, the ventral fin having no fin rays, and there being a long caudal process.

A PAPER was read lately by Mr. H. B. Stocks to the Edinburgh Royal Society (Proc. Roy. Soc. Edin. p. 70), "On Certain Concretions from the Lower Coal Measures, and the Fossil Plants which they contain." The interest which attaches to these concretions, or "coal-balls," is the remarkably perfect state of preservation of the fossil contents, in many cases fine plant-cells and fibres being preserved even without complete petrifaction. Chemically analysed, the petrified wood yields mainly carbonate of lime and iron pyrites, each in the proportion of 48 per cent. The late Mr. Binney suggested that the carbonate of lime was dissolved from shells in the marine strata overlying the concretionary beds and re-deposited on the plants, but, as Mr. Stocks points out, this assumes the lapse of a considerable period of time between the beginning of vegetable decay and the process of petrifaction, a period which would be under ordinary conditions fatal to the preservation of the delicate vegetable tissues. Mr. Stocks thinks that decay and petrifaction went on simultaneously, and hopes to prove the following explanation o the mode of petrifaction: by the process of osmosis water con taining the usual quantity of carbon sulphate in solution, passes through the vegetable tissues of the plant, and sets up a series of chemical changes resulting in the formation of carbonate of lime and iron pyrites. The sulphuretted hydrogen combines then with more iron. The spheroidal shape of the nodules is, he believes, merely due to the deposition of calcium carbonate from a solution heavily charged with organic matter.

THE October number of the *Annals of Scottish Natural History* contains several interesting articles, amongst them being one by Mr. Peter Adair, on the disappearance of the short-tailed field vole (*Arvicola agrestis*), and on some of the effects of the vole plague. This destructive rodent began to be observed in the infested area a few years before 1890; it multiplied with rapidity until the summer of 1892, when the numbers began to decrease, and by the summer of the present year the pest had disappeared. Mr. Adair finds that the disappearance has been general over the whole infested area. On some farms the normal numbers remain, but on others scarcely a vole is to be seen. Various causes have been suggested to account for the disappearance. The drought of last spring and winter may have had some good effect, for the animal is partial to damp

ground. There is, on the other hand, evidence that an epidemic caused the plague to come to an end. But it is the general opinion of the farmers and shepherds of the district from which Mr. Adair obtained his particulars, that the disappearance is due in a great measure to the work of such natural enemies as the owl, kestrel, rook, blackhead gull, and buzzard, the stoat, and the weasel.

The Weather Bureau of Washington has published an elaborate discussion of the climate of Chicago, by Prof. H. A. Hazen, being No. 10 of the valuable *Bulletins* now being issued by that department. The city of Chicago is situated at the south-west of Lake Michigan, whose elevation is about 580 feet above the level of the sea. The earliest observations available were made in 1832, and continued until 1836, after which time they were of a very fragmentary character until November, 1859, since which a continuous series of observations has been maintained, at least as far as regards the temperature. The lake has naturally great influence upon the climate, and this has been investigated in great detail for each separate element. With regard to the winds, the tables show that for the year there is a maximum from the south-west, and a secondary maximum from the north-east. During the cold months there is a marked preponderance of land winds, while in the warm months there is a slight preponderance of lake winds. The mean temperature deduced from twenty years' observations is 48°·6, and occurs about the third week in April and October. The highest temperature occurs about the middle of July, and the lowest the third week in January; for 174 days the temperature is rising, and during 191 it is falling. The cold spell about the middle of May, which is generally observed in the northern hemisphere, is well marked in the 5-- day means. The highest temperature observed was 99°·6 on July 17, 1887, and the lowest −23° on December 24, 1872. The maximum temperature was 90° or over on 121 days during 20 years, and a minimum temperature of −15° or below was only reached 16 times. Accurate rainfall observations can scarcely be said to begin at Chicago before 1867. The annual rainfall from this series is 34·4 inches, and is fairly well spread over each month. A fall of 2·5 inches in a day only occurred 15 times in 20 years. The work contains an abstract of the observers' *Journal* since the occupation of the station by the Weather Service, which includes an interesting account of their experience of the great fire of October 8–9, 1871.

We learn from the report on the administration of the Meteorological Department of the Government of India that the valuable series of meteorological observations which were taken by the late Mr. J. Allan Broun at Trevandrum during the years 1853–64 are being prepared for publication by that department, owing to the action taken by the Royal Societies of London and Edinburgh, and by the Meteorological Council with that view. It is proposed to publish them in three volumes containing (1) hourly observations, (2) comparative observations at various stations on the Travancore Hills, and (3) discussion of the observations. The report shows great activity in the collection of observations from ships entering the Hooghly; these observations are used in the construction of daily charts of the Indian land and sea area, the publication of which began with January this year. The growing usefulness of ordinary weather forecasts is exemplified by the fact that they have been extended to expeditions in the field, and they have been pronounced by the military authorities to have been very successful.

Herr P. Czermak publishes, in *Wiedemann's Annalen*, some beautiful photographs of ascending currents in gases and liquids. For the former a box of rectangular section was used, consisting of plate-glass sides firmly cemented together. At the centre of the bottom was placed a flat spiral, the escape spring of a large spindle clock. The spiral could be heated by the passage of an electric current. A glass tube opened into the box at the bottom, directed towards the centre, for the introduction of smoke. A second glass tube led in at the top, for ventilation or the introduction of a light gas. Tobacco smoke blown in through the lower tube was seen to spread out on the bottom in a uniform layer, provided all parts of the box were at the same temperature. The touch of the hand on one side was sufficient to produce an ascending current and a motion of the smoke towards the warmer side. It was therefore necessary to perform the experiments in a room kept at a uniform temperature. On sending a current through the spiral, the mushroom-like figure first described by Vettin was observed to rise in faultless symmetry. This was photographed by flash-light, and the reproductions show the spiral convolutions to great perfection. Since the contours reflected the greatest amount of light, they stand out well from the dark background, and clearly exhibit the interior structure of the stream-figure. In order to imitate more closely the actual condition of the atmosphere during the ascent of warm air currents, the upper part of the box was filled with coal-gas. The stream-figure then ascended in the usual manner until its vertex reached the lighter stratum. It then became stationary, expanded in the diffusion stratum, and part of the smoke trickled back to the bottom. Sometimes it was found possible to obtain a cloud-like structure, with a dome in the centre and wavy outlines. The figures were more easily produced and photographed in the case of liquids, but the general type remained the same.

Investigations are carried on at the Agricultural Experiment Station, Purdue University, Indiana, on much the same lines as at Rothamsted. *Bulletin* 45 of the Station contains information of interest and importance concerning wheat-growing in Indiana. From field experiments extending over ten years it appears that none of the varieties of wheat tried have any tendency to deteriorate or "run out," provided proper care is exercised. No wheat proved to be "rust-proof," but early wheats were generally less injured by rust than later kinds. Eight pecks of seed per acre gave the best returns at the Station, the average yield for nine years being 30·35 bushels per acre. The best results came from sowings made not later than September 20. The value of crop rotation in maintaining yields of grain has been strongly emphasised, for a comparison of rotating crops with constant grain-cropping for seven years showed an average gain of 5·7 bushels per acre in favour of the former. Another important result obtained was that wheat may be harvested at any time from the dough stage to the dead-ripe condition, without appreciably affecting the weight or yield of the grain. Finally, a comparison of forms of nitrogen as fertilisers for wheat indicated that sulphate of ammonia is better than nitrate of soda or dried blood.

In a former note (June 22, 1893) we have given a sho r account of the means employed by Signor Augusto Righi to obtain electro-magnetic waves of small wave-lengths (about 8 cm.), and also on p. 299, vol. xlviii. we have described some of the experiments he has performed, using waves of this small wave-length. Since then Righi has continued his researches, and has published in the Proceedings of the Royal Academy of Lincei an account of his experiments on the question as to whether the electric force is perpendicular to, or in the plane of polarisation. Trouton, from his experiments on the reflection of electro-magnetic waves from the surface of non-conductors, such as glass and paraffin, has come to the conclusion that the electric force is perpendicular to the plane of polarisation. The reflection of these waves from paraffin, and also from metals, has been studied by Righi, who finds a marked difference in the two cases. In the

case of paraffin his results agree with those obtained by Trouton; when, however, a metal is used as the reflector he finds that the plane of polarisation is parallel to the electric force. The author has measured the refractive index, for oscillations having a wave length of 7·5 cm. of the paraffin used in his experiments. He employed for this purpose an equilateral prism, each face being 20 cm. high and 37 cm. broad, and found 1·4 for the refractive index. The paraffin employed was not of the highest quality, although it was quite white and homogeneous, and had a melting point of 50°·5 C.

DR. OETTEL has continued his researches on the phenomena of the electrolytic deposition of metals (see NATURE, July 6, 1893). In the present paper, which is published in the *Chemiker Zeitung*, he gives the results he has obtained in his investigation of the condition of an auxiliary electrode placed between the two principal electrodes in a copper voltameter. For an auxiliary electrode 86 by 131 mm. in size, being a little smaller than the principal electrodes, he finds that copper is deposited on the side next the anode, and dissolved at the side next the cathode; the quantity dissolved being larger than the quantity deposited in nearly the same proportion as at the principal electrodes. This difference is caused by the electrodes not being composed of pure copper. The deposit on the auxiliary electrode attains as much as 87 per cent. of the deposit on the cathode; but depends on the following conditions:—(1) The relative dimensions of the auxiliary electrode and of the chief electrodes. (2) The absolute size of the electrodes; for, since the copper tends to be deposited chiefly at the edges, the proportion increases when the plates are small.

IN order to ascertain if rifle bullets are capable of carrying infection, Messner (*Münchener med. Wochenschrift*, 1892, No. 23) has been making careful experiments with bullets purposely infected with particular micro-organisms. Bullets thus treated were discharged into tin boxes at a distance of from 225 to 250 metres. These boxes were filled with sterile gelatine peptone, and the channel in the latter made by the passage of the bullet was carefully watched and examined. It was found that in all cases the infected bullets had produced growths of those organisms in the gelatine with which they had originally been brought in contact. In some experiments the boxes, whilst filled with sterile gelatine, were covered over with flannel previously infected with particular bacteria, so that before reaching the gelatine the bullet would first have to pass through the former. Ordinary uninfected bullets were used, but in every instance bacterial growths made their appearance in the subjacent gelatine corresponding to the particular organisms present on the flannel. On the other hand, ordinary bullets, when discharged direct into the gelatine, occasioned only the appearance of moulds and other bacteria usually found in the air. Thus the heat communicated to the bullet during its discharge is not sufficient to destroy any bacteria which may be present upon it; the temperature produced is also wholly inadequate to sterilise any portions of clothing with which the bullet may come in contact, the latter, on the contrary, carrying with it into the wound those bacteria which may be present on the former.

WITH regard to the physiological action of oxygen in asphyxia, more especially in coal mines, a committee of the British Association has arrived at the following conclusions:—(1) In the case of rabbits asphyxiated slowly or rapidly, oxygen is of no greater service than air, whether the recovery be brought about in an atmosphere contaminated by carbonic acid or completely free of carbonic acid, and whether artificial respiration be resorted to in addition or not. (2) Pure oxygen, when inhaled by a healthy man for five minutes, produces no appreciable effect on the respiratory rate and volume, nor on the pulse rate or volume. (3) Oxygen, whether pure or somewhat diluted, produced no effect on one particular patient, who suffered from cardiac dyspnœa of moderately severe type, in the direction of ameliorating the dyspnœa, and, compared with air inhaled under the same conditions, produced no appreciable effect, either on the respiratory rate and volume or on the pulse rate and volume. (4) An animal may be placed in a chamber, the general cavity of which contains about 50 per cent. of carbonic acid, and retained there for a long time without supervention of muscular collapse, provided a gentle stream of a respirable air gas or oxygen, indifferently, be allowed to play upon the nostrils and agitate the surrounding atmosphere.

THE *Quarterly Journal of the Geological Society* (No. 196) has been issued.

MESSRS. DULAU AND CO. have issued a catalogue of works on Lepidoptera, Neuroptera, and Orthoptera.

MESSRS. WHITTAKER AND CO. have published a pamphlet, by Capt. M. P. Nadieine, on a new system of sanitary drainage and treatment of sewage matter.

THE Matabele War has induced Mr. E. P. Mathers to issue a "Map of Mashonaland and Matabeleland." A few facts about the Matabeles and their country give the map additional interest.

WE have received a paper on "Rainmaking," read before the Texas Academy of Science in December 1892, in which Dr. A. Macfarlane discusses professional rain-makers (not the medicine men of the Indians, but their civilised prototypes) and disposes of their theories seriatim.

THOUGH Mr. A. T. Burgess's "First Stage Agriculture" (Joseph Hughes and Co.) is adapted to the Elementary Syllabus of the Department of Science and Art, it should be valuable to all students of agriculture. The author is concise in his statements, so he has been able to give a large amount of information in a small book. A scarcity of illustrations is the book's only fault.

"THE Birds of Michigan," by Mr. A. J. Cook, are described in *Bulletin* No. 94 of the Michigan State Agricultural College. The bulletin is illustrated and contains a bibliography. In the text are recorded the food habits of the birds; so that the economic importance of the various species can be judged. A section is devoted to a statement of the laws that obtain in Michigan for the protection of game. The list is a useful contribution to the ornithology of an interesting region.

A USEFUL book on the "Analysis of Milk and Milk Products," by Prof. Henry Leffmann and Dr. William Beam, has been published by Messrs. P. Blakiston, Son and Co., Philadelphia. The book appeals particularly to American agriculturists, but it may be introduced with profit into the dairy schools springing up in various parts of the country, and professional chemists will be interested in some of the analytical methods described.

MR. HUGH GORDON'S "Elementary Course of Practical Science," part 1, belonging to the series of Science Primers published by Messrs. Macmillan and Co., is worthy of introduction into all elementary and continuation schools. The experiments described are of a very simple nature, and refer to every-day phenomena. The pupil who conscientiously works through the little book will certainly have impressed upon him the importance of exactness, and will thus be given the best foundation of a scientific education.

ANOTHER book on practical physics is "Lessons and Exercises in Heat," by Mr. A. D. Hall (Rivington, Percival and Co.) The book contains a series of lessons and exercises, and is

suitable for use as a supplement to lectures and demonstrations. The experiments described will impress the student with the fact that "science is measurement," hence they are of the right kind, for it is doubtful whether showy experiments are of any educational value. Schools and university classes requiring a good and accurate handbook of heat for the physical laboratory would do well to adopt Mr. Hall's work.

MESSRS. LONGMANS AND CO. have just published, for Dr. F. Clemow, of the English Hospital, Cronstadt, "The Cholera Epidemic of 1892 in the Russian Empire." The author states in his preface that to the English medical world Russia is almost a closed book. The reason of this is that, in consequence of the difficulties of the Russian language, medical news from that country is rarely taken from the original source. Dr. Clemow, therefore, having a knowledge of Russian, set himself to give a plain, unvarnished account of the epidemic of cholera which last summer swept over the Russian Empire, and to bring together information bearing upon the subject *directly* from the most authentic Russian sources. He seems to have spared no pains to get the statistics as full and trustworthy as possible, and was assured by the authorities that, notwithstanding the difficulties attending their efforts to obtain proper returns from regions such as Central Asia and Siberia, in no case did the error exceed 10 per cent.

CARBIDE of silicon, SiC, the beautifully crystalline sapphire-like substance whose preparation by M. Moissan with the aid of the electric furnace was described in our note of October 12, p. 572, forms the subject of a communication to the current publication of the *Zeitschrift für Anorganische Chemie*, by Dr. Mühlhäuser, of Chicago, whose preparation of the carbide of boron formed the subject of our last week's chemical note. It appears that Dr. Mühlhäuser had already completed a long and very elaborate research upon the preparation of this interesting compound upon a scale of considerable magnitude, for the ultimate purpose of its manufacture, before the communication of M. Moissan appeared. The mode by which it may be obtained in large quantities was perfected some time ago by Mr. Acheson, and Dr. Mühlhäuser now gives details of the process, together with considerable additions to our knowledge of its chemical and physical nature. The process essentially consists in heating a mixture of silica and carbon to the temperature of 3500° by means of the electric furnace, when carbon monoxide escapes and silicon carbide is produced.

$$SiO_2 + 3C = SiC + 2CO.$$

Silicate of alumina may be employed instead of silica with equally good results. The crystals obtained possess many of the properties, particularly the hardness, of the diamond. According to the purity of the materials employed in their manufacture they are colourless, or coloured yellowish green, bluish green, or pale blue. The name carborundum is suggested for the substance. Upon the large scale the cheaper materials sand and coke are employed, with the addition of common salt as a flux. The latter acts mechanically, causing the unattacked portion of the ingredients to bake together, thus facilitating the separation of the crystals; it also prevents loss of carbon by surface oxidation. One hundred parts of the powdered coke are mixed with one hundred parts of sand and twenty-five parts of salt. The mixture is placed in an electric furnace built of highly refractory fireclay. The electrodes are inserted through apertures at the ends of the furnace, and are connected with a central bar of carbon, the high resistance, round which the mixture is closely packed. The electrodes are in immediate connection with a powerful current transformer, which is connected in turn with an alternating current dynamo. The carbon high resistance bar is raised by the current to an intense white heat, which is in turn communicated to the mixture. Gas is rapidly evolved from the mass, and yellow and blue flames dart out in all directions. As the heat increases the flame concentrates about one position until the fused salt rises to the surface, when an energetic action occurs, the gases eventually forcing their way through the liquid crust and heaping it up in the form of a crater, from which a high flame shoots up surrounded at its base by dense white clouds of vapour of salt, and eventually the remainder of the salt wells forth from the crater like veritable lava, carrying the dark impurities along with it. The interior of the crater, where the reaction is proceeding, is now seen to be white hot. The eruption soon commences to subside, the flames cease to appear, the outer crust hardens, and the reaction is complete.

THE product of this remarkable reaction is an ellipsoidal hardened mass, surrounding the carbon high resistance, and is found upon making a section to consist of six distinct layers. The first, close against the carbon bar, is a zone of graphite, which occurs in the form of hollowed hexagonal plates, pseudomorphs of silicon carbide, from which they are produced by dissociation at the extremely high temperature in the neighbourhood of the bar, silicon escaping as vapour. The second and by far the largest zone consists of the crystals of silicon carbide. They are largely found in elongated aggregates, radiating in all directions from the axis of the ellipsoid; the individuals forming the aggregates are bluish or yellowish-green, and of all sizes up to crystals a centimetre in diameter. Numerous isolated and highly perfect crystals of considerable size and great beauty are likewise found between the aggregates. Surrounding this zone of crystals is a narrow zone of amorphous carbide of silicon, outside which is found a layer of nodules of minerals produced from the impurities during the reaction; the fifth layer consists of the remains of uncombined mixture, and the sixth the crust of common salt. The crystals obtained by employing silicate of alumina are usually colourless or pale blue, and have been employed by M. Nikola Tesla in his new lamp for the transformation of electrical waves into waves of light. The powdered crystals explode violently when heated with potassium and lead chromates, but burn quietly with chromate of lead alone, forming dioxides of carbon and silicon. The powder exhibits a vivid greenish-yellow luminosity when heated in a platinum crucible. It is only very slightly attacked by the oxygen of the air under these circumstances, only 0·5 per cent. uniting in an hour. The fine powder, moreover, remains suspended in water for months without subsiding, although the specific gravity of the carbide at 15° is 3·22.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Mr. Robert Gallon; a Chestnut-eared Finch (*Amadina castonotus*) from Australia, a De Filippi's Meadow Starling (*Sturnella defilippi*) from South America, presented by Mrs. Kemp-Welch; two Laughing Kingfishers (*Dacelo gigantea*) from Australia, presented by the Executors of the late Mr. Fred Burgess; a Punctured Salamander (*Amblystoma punctatum*) from North America, presented by Mr. J. H. Thomson, C.M.Z.S.; four Common Toads (*Bufo vulgaris*) from Jersey, presented by Mr. J. Stanton; two White-handed Gibbons (*Hylobates lar*. ♂ ♂), a —— Bulbul (*Hypsipetes* ——) from the Malay Peninsula, a Red and Yellow Macaw (*Ara chloroptera*) from South America, five Green Lizards (*Lacerta viridis*), three Black-spotted Toads (*Bufo melanostictus*), four Schlagintweit's Frogs (*Rana cyanophlyctis*) from Ceylon, two Slow-worms (*Anguis fragilis*), three Fire-bellied Toads (*Bombinator igneus*) European, deposited; a Bar-tailed Godwit (*Limosa lapponica*), two Dunlins (*Tringa alpina*) British, purchased.

OUR ASTRONOMICAL COLUMN.

Brooks' Comet.—Dr. F. Bidschof has computed the following elements and ephemeris for the comet discovered by Mr. W. R. Brooks, on October 16:—

T = 1893 September 19·6929 Berlin mean time.
☊ = 175° 1·0 ⎫ Mean
ω = 348 30·7 ⎬ eq.
i = 129 54·6 ⎭ 1893·0
log q = 9·91335

Ephemeris for Berlin Midnight.

1893.	R.A. app. h. m. s.	Decl. app. ° ′	log r	log Δ	Brightness
November 2	12 45 59	+24 35·9	0·0600	0·1913	0·88
6	12 53 13	27 51·8	0·0782	0·1788	0·85
10	13 1 12	31 21·1	0·0961	0·1662	0·83
14	13 10 2	+35 4·6	0·1137	0·1539	0·81

The brightness of the comet on October 18 has been taken as unity.

The Planet Jupiter.—At the present time Jupiter is a fine object for observation, his declination being between 18° and 19° north of the equator. Coming into opposition on November 18, telescopes of moderate power can be used effectively for observing the belts, small spots, and other fine details. Large instruments—that is, those having an aperture of 15 or 16 inches or more—may be used also for observations of the 5th satellite. Assuming the period of this satellite to be 11h. 57m. 21·88s. with a probable error of about a second of time according to Mr. Marth, the following are the approximate times of elongation:—

Greenwich Time.

		East. h. m.		West. h. m.
Nov. 2	...	9 9 p.m.	...	3 8 a.m.
6	...	8 47	...	2 46
10	...	8 24	...	2 23
14	...	8 2	...	2 1
18	...	7 40	...	1 39
22	...	7 18	...	1 17
26	...	6 56	...	12 55
30	...	6 34	..	12 33

The Wave Lengths of the Nebular Lines.—Last week we referred to Prof. Keeler's paper, read at the congress of Astronomy and Astro-Physics at Chicago, and we may add here a few words with regard to the results it included, as they are of importance. This paper, on "The Wave-lengths of the two Brightest Lines in the Spectrum of the Nebulæ" is the outcome of a series of measurements made with the 36-inch refractor and the large spectroscope of the Lick Observatory, the dispersion employed being equivalent to twenty-four 60° flint prism. The "normal position" of a nebular line is defined as the position of the line in the spectrum of a nebula at rest relatively to the observer. The results with respect to the two chief nebular lines are—

Normal position of the chief nebular line on Rowland's scale ... ... λ 5007·05 ± ·03
Normal position of the second nebular line on Rowland's scale ... ... λ 4959·02 ± ·04

Prof. Keeler considers the greater part of this probable error to be due to comparisons with the third line, which could not be observed so accurately. From all the observations he finds that the motion of the Orion nebula referred to the sun is + 11·0 ± 0·8 miles per second, and the wave-length of the chief line in this nebula, corrected for the earth's orbital motion, is 5007·34 ± ·013.

GEOGRAPHICAL NOTES.

Yet another plan for polar exploration is announced with no definite purpose of pushing on to the pole, although that may incidentally be reached. Mr. Robert Stein, of the U.S. Geological Survey, proposes establishing a station at the south end of Ellesmere Land, which will be kept in touch with the outer world by the whalers hunting in Baffin Bay. Here a number of observers will live gaining experience in Arctic travel, and from this base "a fan of secondary stations" will be pushed out a hundred miles or so further north, where comfortable houses will be built and frequent communication kept up with headquarters. From each secondary station the staff of five hardy observers will travel northwards, combining science with sport, and even when tracking the musk-ox or white bear each explorer will carry his "four-pound aluminium theodolite" and "make game of the heights and bearings of the mountain peaks." We fear that if this expedition, or rather system of exploration, is really set on foot, its difficulties will become much more real than they now appear. In any case it would be wise to postpone work on so large a scale until the two well-equipped expeditions already in the field have added their contribution to our knowledge of Arctic conditions.

M. E. de Poncins, who is travelling in Central Asia, has written some interesting letters to the Paris Geographical Society. In the latest, dated from Chajan, in the Pamirs, on July 9, he mentions the curious fact that while in Europe he has repeatedly suffered from mountain sickness on Mont Blanc and Monte Rosa, he eats and sleeps at 4500 metres in the Pamirs just the same as at sea-level. In crossing snow-passes at 5750 metres his horses caused some trouble, but with this exception he found the Pamirs a pleasant region where it was easy to get about in summer.

The Russian Government has organised a new province in Siberia under the name of Anadyr. It occupies the extreme north-east of Asia, and is very thinly peopled, mainly by natives, Koriaks, Kamchadales, Chuchis, &c., the last named being the most numerous and the least uncivilised.

Dr. E. v. Drygalski, who has spent eighteen months in North-West Greenland studying the phenomena of Arctic glaciers, has returned to Europe, and his report of the work done by his expedition will be expected with much interest.

A novelty in political boundary lines is reported in *La Géographie*, which states that the frontier between Turkey and Servia is to be marked throughout its length by a wire fence.

The November number of the *Geographical Journal* is rich in new contributions to geography and exploration. The Earl of Dunmore's paper on the Pamirs and Central Asia occupies the first place.—The Rev. J. A. Wylie gives an account of a journey through Central Manchuria, with many interesting notes on places and people, and a detailed itinerary which must prove valuable to subsequent travellers.—Lieut. B. L. Sclater writes a detailed report on routes and districts in Southern Nysaland, illustrated by a new map of the district east of the Shire as far as the Milanji Mountains, largely compiled from his own prismatic compass surveys.—Mr. Theodore Bent communicates a letter from Mr. Swan, who is now in Mashonaland, giving an account of fresh ruins recently visited on the Lotsani and Lundi Rivers, the "orientation" of which to the setting solstitial sun he believes he has established.—Mr. W. S. Bruce and Dr. C. W. Donald publish a preliminary report of their observations during a voyage toward the Antarctic Sea, and Dr. Schlichter gives his paper on the determination of geographical latitudes by photography.

INSTITUTION OF MECHANICAL ENGINEERS

On Wednesday and Thursday of last week, October 25 and 26, a general meeting of the Institution of Mechanical Engineers was held in the theatre of the Institution of Civil Engineers, in Great George-street, Westminster; the President, Dr. William Anderson, occupying the chair. Dr. Anderson retires in rotation this year, and Prof. Alexander B. W. Kennedy, F.R.S., is proposed as his successor. There were two papers down for reading, as follows:—"On the Artificial Lighting of Workshops," by Mr. Benjamin A. Dobson, of Bolton; and "On the Working of Steam Pumps on the Russian South-Western Railways," by Mr. Alexander Borodin, Engineer-Director.

Mr. Dobson's contribution was an interesting and valuable paper, in which he described the results of inquiries he had made with a view to obtaining the best mode of artificial illumination for the large workshops of his engineering establishment at Bolton. Mr. Dobson's works are engaged in producing textile machinery, more especially that for cotton-spinning. Many parts of such machinery require to be finished

in the highest manner, and with mathematical accuracy. In order to accomplish this a good light is necessary, but unfortunately that is a thing Mr. Dobson can seldom get from natural sources at his works. We do not as a rule expect to find engineers and manufacturers exclaiming against the smoke nuisance; we rather look to hear such things from those who cultivate the gentler arts. It is therefore, perhaps, worth while to quote a few passages from Mr. Dobson's paper, in which he speaks of the state of the atmosphere in Lancashire:—

"Although Lancashire coal has a number of excellent qualities, yet it is one that makes the most smoke of any. A large portion of the Lancashire manufacturing industries, great and small, date from a number of years back, when smoke-consuming and smoke-preventing apparatus had not yet been devised; and many of the factories are working at the present day under pretty much the same conditions as when they started. Hence the atmosphere in all manufacturing towns in Lancashire is heavily charged with unconsumed carbon, producing an excess of cloud and fog, which, while inducing an excess of rain, acts also as a screen against the rays of the sun, and thus does a double injury to the neighbouring agriculturist, the producer of the country's native wealth. A circle of thirty miles radius around Manchester is said to include a larger population than an equal circle around any other place in the world; and within this circle, about twelve miles north-west of Manchester, lies Bolton, the town with which the author is best acquainted, where all winds, except the west and north-west, bring the surcharged atmosphere from other manufacturing districts, producing at any season of the year, if the wind happens to be slight, a sky ranging from dull lead to dark brown. For four years in succession it has occurred at the writer's works, that on June 21, the longest day, the gas in every room, amounting to nearly 7500 jets, has had to be lighted by eleven o'clock in the morning, and has remained lighted until work ceased; and this has occurred also in other towns, in weather that ought to have secured abundant sunshine. To such an extent does gloom prevail that in clear weather the effect of bright sunlight becomes even distressing to the eyesight, simply from the rarity of the contrast."

In endeavouring to improve the lighting of his shops, Mr. Dobson naturally turned to electricity. Incandescent lamps were tried, but these were not a very great improvement in illuminating power over gas; whilst with the arc lamp the shadows were so hard and strongly defined that the workmen preferred a very much weaker illumination, if more diffused. When travelling on the Continent, Mr. Dobson visited some cotton mills, and here he found what seemed a very perfect system of illumination. Arc lamps were used, but they were placed in an inverted position to that which is usual, the negative carbon being above, and the positive carbon below. This, of course, threw the greater part of the light rays upwards, as most of the illuminating power proceeds from the crater of the positive carbon. The ceiling is kept well whitewashed, so that the light thrown up is again reflected downwards. The sides of the rooms are also whitewashed, in order that a reflection may come from them. The result is that, without any definite source of illumination being observable, the whole room is flooded with a well-diffused light. Mr. Dobson had very kindly arranged to have one of these lamps in the large visitors' room of the Institution of Civil Engineers, so that members were able to judge of its efficiency for themselves. The result was very perfect in regard to absence of shadows. One could stand in any part of the room, facing any way, and read a book or paper without any very perceptible shadow being thrown; indeed, the diffusion of light appeared to us as good as in the open air. Such a result is of the greatest importance, and it is to be hoped that libraries and reading-rooms especially will in future largely adopt this system; or at any rate, that it will be introduced to the exclusion of the direct arc lighting, like that adopted with such unpleasant results in the reading-room of the British Museum. In regard to the cost, Mr. Dobson cannot speak positively on the subject, not having yet sufficient data to go upon, but he anticipates that it will be higher than gas at 2*s.* 8*d.* per thousand, which is the price in Bolton. There will, however, be a much larger volume of light than when the gas was used, and the advantages of the system, in his opinion, altogether outweigh any possible additional cost. In the discussion which followed, Mr. A. P. Trotter gave a good popular explanation of the advantages of a dead white surface for reflecting light, as compared to that of a looking-glass or bright surface. Good white blotting-paper, he said, reflects back 82 per cent. of the light cast upon it. Many persons are under the impression that looking-glass must be a better reflector than paper or a whitewashed surface, because, with looking-glass, a strong shadow can be cast, while from a dead surface no heavy shadow is obtained. The reason, of course, is not so much that the reflected light is less from the dead surface, but that the reflection is concentrated in the case of the looking-glass; with paper or whitewash it proceeds from a vast number of points.

A modification of this system of reflected light, which is of interest, has been adopted by Mr. Aspinall, the chief engineer of the Lancashire and Yorkshire Railway, at the Horwich shops, where the rolling-stock for the line is produced. In these shops the roof is not adapted for putting in large whitewashed reflectors above the lamps, the jibs of travelling cranes, belting, shafting, &c., being in the way; but Mr. Aspinall, having seen the very perfect illumination obtained by Mr. Dobson at Bolton, determined to see if he could not obtain a modified result. He therefore inverted his arc lamps so as to get the positive carbon below, as in the case of the Bolton installation, and the major part of the light would be thrown towards the ceiling. Above the lamp, and therefore not shielding it from view, was a whitewashed screen of boards, acting as a reflector. The effect was far superior to that of the ordinary method of arc lighting, where the dazzling stream of light pours upon the spectator to the derangement of his eyesight, and at the same time casting heavy and impenetrable shadows. This arrangement, however, is inferior to the complete system, as described by Mr. Dobson, but may be taken as a very good substitute where, from local causes, the entirely reflected principle cannot be adopted.

Mr. Borodin's paper on Steam Pumps was read on the second day of the meeting, and led to a fairly long discussion. The author gives details of a number of pumps tested in order to find their efficiency under ordinary working conditions. The paper has a commercial rather than a scientific interest, to this extent—that it shows the manufacturers how badly machinery may work; for instance, a pump manufactured by an English firm of very good repute only gave 2953 foot lbs. of work done per lb. of steam, when pumping against a head of 33 ft. and the steam pressure being 90 lbs. Supposing the trial conditions to be properly observed—which there is no reason to doubt they were in the present instance—such a result could only be due to the pump being in extremely bad condition, owing to neglect or ill-usage. It had been in use for a number of years. One meets with the same thing—perhaps to a greater extent—in steam engines where the fuel consumption of 30 or even 40 lbs. per one horse-power per hour has been recorded. Mr. Borodin's paper is useful as supplying awful examples for pump users, and at the same time it opens up the very wide question of the value of trial trip efficiencies. To take another instance, that of war ships, a very high speed may be obtained on trial with picked coal, picked stokers, engines thoroughly overhauled, and, in fact, every possible precaution taken to procure efficiency. Naval captains are apt to say, "We would like to know what our ship will do under fair working conditions in action, rather than what she may be made capable of by tuning her up to concert pitch." That is a very good argument for the captains, but where are we to draw the line? It is impossible to lay down what are the fair conditions of ordinary service for any class of vessels—how bad the coal should be, how inefficient the stokers, how rough the weather. Our only course is to get the highest possible result in every case, and then make such allowance as experience, or common sense, would dictate. The same thing may be said with regard to the pumping machinery dealt with by the author. For instance, a pulsometer referred to in the paper was stated to require 860 lbs. of steam per hour for a certain duty; whilst experiments made by Prof. T. Hudson Beere, with a pulsometer in good order, gave the pounds of steam required for a similar duty as 147·6. Now, it will be obvious that if a contractor requires a convenient pump like the pulsometer, and is prepared to pay somewhat for the suitability in the matter of economy, he need not take 860 as his figure of merit, when 147·6 is the trial trip efficiency, although he may undoubtedly have to make some allowance upon the latter figure.

The paper was favourably received by the meeting, and will no doubt add to the attractiveness of the volume of Transactions in which it will appear.

The meeting concluded with the usual votes of thanks.

THE ARBUTHNOT MUSEUM, PETERHEAD.

THE visitor to Peterhead in past years may have had his or her attention directed to the Arbuthnot Museum, and may have ventured into the hall which then contained the very interesting but well-mixed collection.

The founder of this museum, Mr. Adam Arbuthnot, was born in September 1773. During his years of business as a merchant in Peterhead, and after he retired, he kept gathering at objects of antiquity and natural history, and amassed an immense and valuable collection, all of which he bequeathed to the town at his death in 1850. Some years later the museum of antiquities, minerals, &c. collected by the members of the Peterhead Institute, was added. This last contained a very fine and extensive collection of local shells by the late Mr. Dawson, who was a schoolmaster in Cruden. Since then many smaller but important donations have been made, notably by whaling captains. The Rev. Mr. Yuill, late Free Church minister of Peterhead, contributed the large majority of the invertebrate fauna.

It had become apparent that better accommodation was required, and a complete revisal of the whole collection. There is no necessity here of detailing how this was gradually arrived at. With bazaars, and by means of a handsome contribution made by Mr. Carnegie, Peterhead was enabled to adopt the Free Library Act, and on a site obtained, a very handsome and suitable building was erected, with provision for a free library and reading-room, museum, and art gallery. The two rooms devoted to the museum are large and well-lighted, and the collection has been completely rearranged. The whole building was opened on Wednesday, October 11.

The museum is now in a very different condition. One of the rooms contains the antiquities and ethnographical exhibits, the other the natural history collection. Local and foreign objects have been separated in both rooms as far as was possible. And now the visitor may begin in the antiquities room and see the stone implements, the urns, and the mediæval finds of a local character, and the curiosities from different parts of the world, all placed in a rational order. The rich collection of domestic and other articles from Greenland are all together at the far end of the room. A very valuable collection of coins is also arranged in excellent order in this room. It may be interesting to note that the British coins are so arranged in movable glass panels that the visitor can see both sides by turning the panels round. The ancient swords, African spears, and the like have been grouped on the walls. Not only is the room in the manner of its arrangement worthy a visit, but many of the objects are of considerable value and interest.

The same is true of the larger natural history room. There is a very good collection of minerals, polished granites from many localities, local seaweeds, lichens, mosses, and the invertebrate division of the zoological collection is also rich in many of the orders. These specimens are all arranged in large double-floor cases, a feature in which is the upright middle case. Spirit and branching specimens are thus shown to an immense advantage from both sides. Lightness of effect is secured by using plate-glass shelves.

It may be interesting, moreover, to point out that one or two of the Sertularians and a Ray's bream have been obtained, prepared, and presented by Mr. C. W. Peach.

The fishes are arranged in a wall case, and surmounted by a group of the "saws" of the saw-fish. The amphibia and reptiles are arranged in a corresponding case, which is surmounted by turtle shields. The crocodiles, &c., are arranged on the wall near this, above the very handsome case of birds. In this last case, as in the rest of the museum, all the foreign specimens are made to keep company. The mammals are arranged in one of the old cases, and near them all the Greenland specimens are grouped together. Plate-glass shelves have been used throughout.

Very many valuable objects claim the attention in this section. There is a group, for instance, of deers' horns (mostly red deers') over the door, which have been picked up in the mosses around Peterhead, and which measure more in diameter than the recent ones. Among the fishes are many that could be mentioned as occurring at Peterhead. There are several fœtuses of whales, walruses and seals, including a large one of the Greenland whale. Two very nice cases, exhibiting the characteristics of foxes and badgers, are the work of the Aberdeen naturalist Mr. Sim. A similar case of sea birds was made by a local naturalist, Mr. McBoyle, from whom, too, many of the local birds have been procured. It is to be hoped that some of the groups, such as the Crustacea, will not be lost sight of by the members of the Buchan Field Club, whose interest in the museum should be a direct and helpful one.

This is not the only collection in Aberdeenshire. It has been my pleasure to meet some enthusiasts who have more or less exhaustive collections of antiquities, insects, birds, &c.; but it is to be regretted that there is no good public museum in Aberdeen itself; its situation is one that would be unequalled almost in interesting such collectors in a very large district. Moreover such a museum, if ever formed, would require to provide for a good technical display illustrating agricultural, fishery, and granitic industry. ALEXANDER MEEK.

THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY.

THIRTY years ago Dr. William Barton Rogers, the then Director of the Geological Survey of Virginia, and a Professor in the University of that State, founded the Massachusetts Institute of Technology, Boston. Dr. Rogers has since died, but the Institute has grown, and is now the largest scientific and technical school in the United States, and one of the largest in the world. By the catalogue of 1892–93, the number of students was 1060, and the number of teachers 125.

An account of the character, equipment, and work of the Institute has recently been published, and from it the following facts have been obtained. The prospectus is illustrated by a number of fine pictures, three of which have been sent to us for publication.

The Institute is remarkable for the great variety of its courses. In it are taught the sciences and their applications to the arts, the studies being divided into thirteen four-year courses, as follows:—(1) Civil engineering, including railroad engineering, highway engineering, bridge building, and hydraulic engineering; (2) mechanical engineering, including steam engineering, mill and locomotive engineering; (3) mining engineering and metallurgy; (4) architecture; (5) chemistry; (6) electrical engineering; (7) biology; (8) physics; (9) general studies; (10) chemical engineering; (11) sanitary engineering; (12) geology; (13) naval architecture. Agriculture is not included in this list, on account of its being provided for in a State College at Amherst.

In the four years required for graduation, it is sought:—

(1) To make the pupil observant, discriminating, and exact.

(2) To develop in him a taste for research and experimentation on the one side, and for active exertion on the other.

(3) To give him the mastery of the fundamental principles of mathematics, chemistry, and physics, which underlie the practice of all the scientific professions.

(4) To equip him with such an amount of practical and technical knowledge, and to make him so familiar with the special problems of the particular scientific profession at which he individually aims, as to qualify him immediately upon graduation to take a place in the industrial order.

The chief and dominating feature of the Institute, from the material point of view, consists of its numerous large and well-equipped laboratories. The buildings of the Institute, in addition to drawing, recitation, and lecture rooms and libraries, comprise eight laboratories, or groups of laboratories. The Rogers Laboratory of Physics comprises seventeen separate rooms. It includes a laboratory of general physics devoted to instruction in the principles of physical measurement, a laboratory of electrical measurements, devoted chiefly to advanced electrical work; a laboratory of acoustics, one for optical work, and another for photography. In addition to these, there is a dynamo-room and several laboratories of electrical engineering.

The dynamo-room (Fig. 1) is provided with a Westinghouse engine of 75 horse-power, the sole use of which is to furnish the power to drive the plant of dynamos. This plant, besides a number of smaller machines, comprises a 500 light alternating current Thomson-Houston dynamo, with transformers, a 150 light Edison dynamo, a 200 light Thomson-Houston direct current dynamo, a 60 light Weston dynamo, a 3 arc-light Brush dynamo, a United States 300 ampere low voltage dynamo for electrolytic work, and a Siemens' alternating arc-light dynamo. From time to time other large machines are temporarily placed here for purposes of study by the students. The wires from

this room are carried to all parts of the building for experimental purposes, as well as for use in illumination.

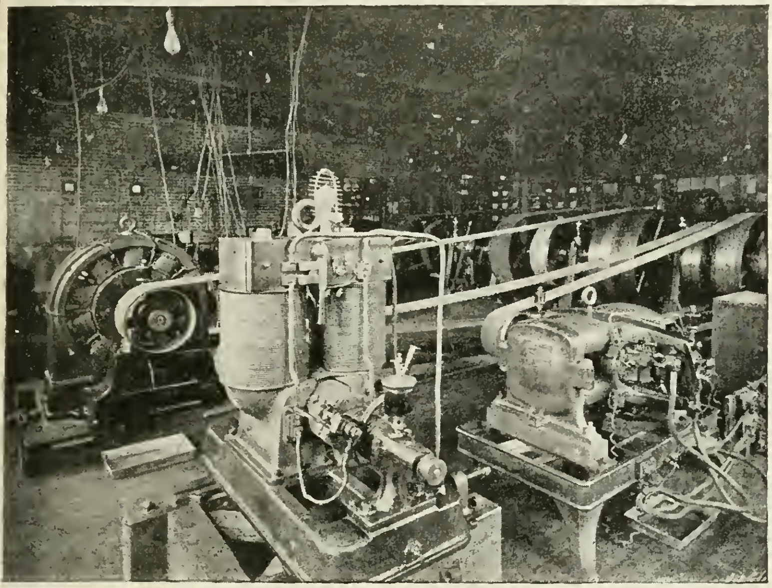

FIG. 1.—Dynamo Room.

The Kidder Chemical Laboratories are just as well-equipped as the Rogers Laboratory of Physics. They comprise eighteen laboratories, four lecture-rooms, a library and reading-room, balance-rooms, &c.; in all, thirty rooms. There is a laboratory of general chemistry with 133 working tables, each of which has under it three complete sets of drawers and cupboards; a laboratory of analytical chemistry, with 108 benches; an organic laboratory having benches for twenty-six students; two laboratories of sanitary chemistry, in which, since 1887, 10,000 samples of water have been analysed for the Massachusetts Board of Health; a laboratory for gas analysis, and three for industrial chemistry, besides a number of smaller ones.

The John Cummings Laboratory of Mining Engineering and Metallurgy comprises laboratories for milling, for concentrating, and for smelting ores, as well as for testing them by an assay and by the blowpipe, and a library comprising the most important literature of the subject.

The engineering laboratories comprise laboratories of steam engineering, of hydraulics, a laboratory for testing the strength of materials, and a room containing cotton machinery.

The most prominent feature of the steam laboratory (Fig. 2) is an Allis triple-expansion engine, having a capacity of about 150 horse-power when running triple, with 150 lbs. initial pressure in the high-pressure cylinder.

The laboratory also contains a 16 horse-power Harris-Corliss engine, and an 8 horse-power engine used for giving instruction in valve-setting. In addition to these, there is a great variety of apparatus, including condensers, calorimeters, injectors and ejectors, steam pumps, &c., directly connected with studies in steam, also apparatus for testing the efficiency of transmission of power and for measuring the power transmitted.

The hydraulic laboratory (Fig. 3) contains a closed tank, 5 feet in diameter and 27 feet high, extending from the basement under the lower floor to the upper part of the room on the second floor. This is connected with a stand-pipe, 10 inches in diameter and over 70 feet high, so arranged that the water may be maintained at any desired point, glass gauges along the stand-pipe serving to measure the height. The stand-pipe is connected with a steam pump, with a rotatory pump, and with the city supply. On the sides of the large tank are the connections for the various hydraulic apparatus, including apparatus for measuring the flow over weirs; through various sizes and shapes of orifices; through hose-nozzles; through different sizes of pipe, with the several varieties of obstructions that occur—namely, diaphragms, couplings, elbows, T's, bends, valves, &c. Also connected with the tank, or with a centrifugal pump, is a Swain turbine, so arranged that measurements can be made of the power transmitted under various heads and with different openings of gate.

The most important feature of the biological laboratory of the Institute is the opportunity of studying ferments, fungi, algæ, bacteria, and other low forms of life. Courses are also provided in general biology, microscopy, comparative anatomy and embryology, physiology and histology.

The Institute possesses a laboratory of mineralogy, lithology, structural geology, and economic geology, but it is neither so extensive nor so well equipped as most of the laboratories already named.

A praiseworthy feature of the Institute's curriculum is that during the last term of his course every student who is a candidate for a degree spends a large portion of his time in the preparation of a thesis upon some chosen subject. This is always of the nature of an experimental research, and may be either purely scientific or technical in its nature. In many cases the results of this work have been of such a character as to merit

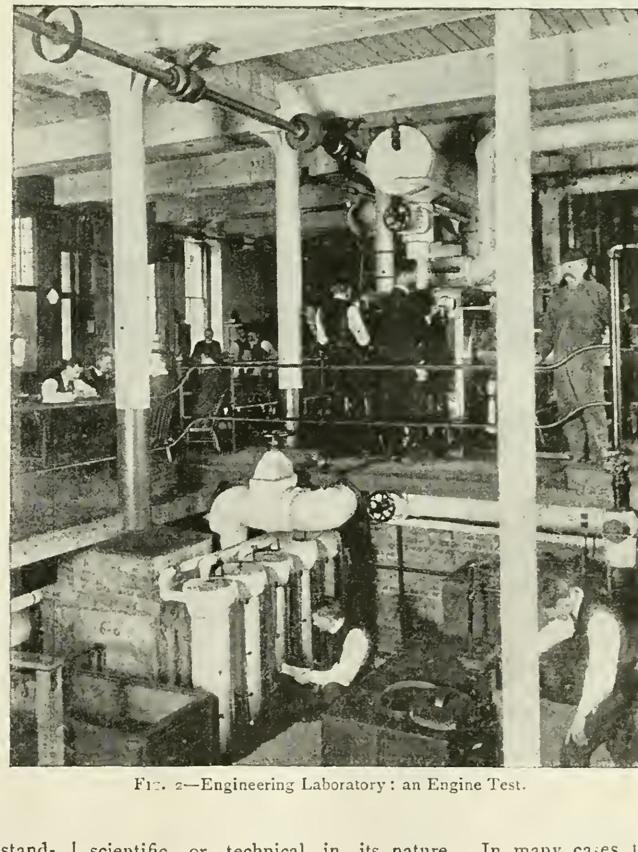

FIG. 2—Engineering Laboratory: an Engine Test.

publication, and a considerable number of such papers have appeared in scientific and technical journals.

A high value is attached to the thesis work; and rightly. In it the student is placed in the attitude of an independent investigator. He is thrown to a large extent upon his own resources in devising methods of investigation and in finding means of overcoming the difficulties that always arise in original work. Such individual aid is given to each student as is necessary to keep him from too great loss of time from using wrong methods of procedure, without, on the other hand, giving him such specific directions as would entirely deprive his work of originality. He thus acquires a knowledge of the patience, care, and time which it is usually necessary to spend upon the experimental solution of any new and untried problem. This early training of investigators has produced excellent results. A register of the publications of the Institute and of its officers, students, and alumni, between 1862 and 1882, was compiled by

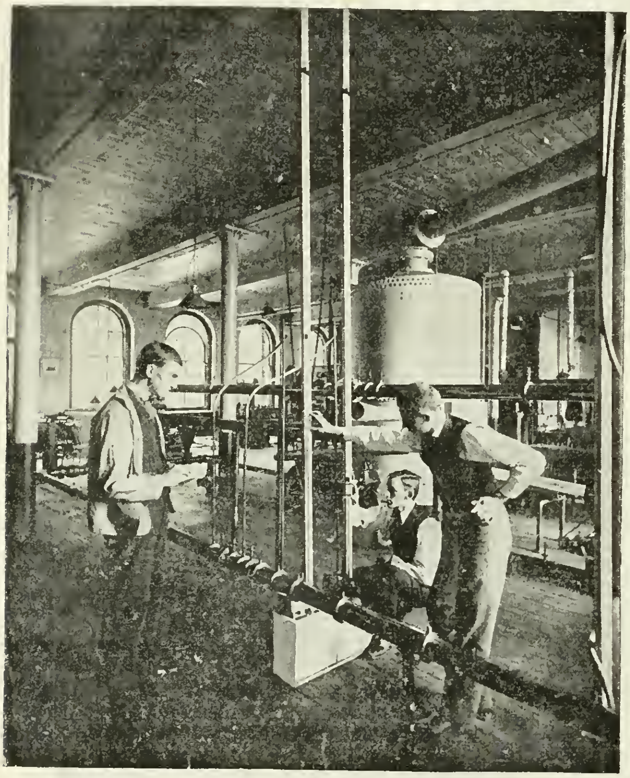

Fig. 3.—Hydraulic Laboratory.

Prof. W. R. Nichols, and has been brought up to date by the late Prof. L. M. Norton and Prof. A. H. Gill. The list includes books, pamphlets, reports, contributions to periodicals—everything, in fact, except contributions to daily newspapers—made by the the teaching staff during their connection with the school, and by students during their connection with the school and in after life. As Prof. Gill remarks, no truer index of the value of an educational institution can be found than the work which its alumni have done and are doing, and when we say that the total number of titles of communications given in the list is nearly 2,900, thirteen hundred of which have been added since 1888, it will be agreed that the system of training at the Massachusetts Institute of Technology is one that gives a love of investigation to the students; and to the man of science this desire to extend natural knowledge should be the end and aim of all scientific education.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—At a meeting of the Junior Scientific Club, on Friday, October 27, Mr. M. D. Hill, of New College, was elected President for the current term. Mr. E. S. Goodrich exhibited some recent additions to the University Museum, including a specimen of Palæospondylus, a specimen of Indris brevicandatus, and the brain of "Sally," the chimpanzee, who was so well known at the Zoological Gardens. Mr. Wynne-Finch, of New College, read a paper on mining; and Mr. Gordon, of Keble College, read a paper on the effects of temperature on the incubation of eggs.

The Ashmolean Society held a meeting on Monday, October 30, when Mr. A. G. Vernon Harcourt read a paper on the properties of ferrous chloride, and Dr. W. B. Benham one on the effects of sedentary life on certain annelids.

The Junior Scientific Club seems to have ousted the older and more senior Ashmolean Society almost completely. At the meetings of the latter, which offers communications of at least equal, perhaps of greater, interest than the Junior Society, the attendance seldom reaches a dozen, and of these a large proportion consists of ladies who are more or less directly interested in the lecturer. The attendance at the Junior Scientific Club, on the other hand, is always large, and frequently exceeds fifty. The reason of this disparity is not easily found. Some people attribute it to the lesser formality of the proceedings of the younger society, and to the fact that smoking is permitted during the meetings.

The Sherardian Professor of Botany announces a course of six lectures on forestry, to be given by Dr. J. Nisbet, at the Botanic Garden, daily from Monday, November 6, to Saturday, November 11, inclusive.

CAMBRIDGE.—The Engineering Laboratory Syndicate ask for a grant of £1000 to enable them to complete the buildings required for the accommodation of the department. From private sources nearly £5000 have been subscribed for the purpose, but this is insufficient for the whole of the work in contemplation. Prof. Ewing reports that no less than seventy-four students have entered for courses in engineering during the present term; and it is very desirable that their work should not be hampered by delay in providing the necessary rooms for their accommodation. It had been hoped that subscriptions towards so valuable an extension of the scientific equipment of the University would flow in liberally, but the stream of benefaction seems for the present to have dried up.

The scheme for examinations in agricultural science will come before the Senate for decision on November 9. Already a note of dissent has been sounded by a well-known theological graduate.

Mr. R. A. Sampson, Fellow of St. John's, has been appointed Professor of Mathematics at the Newcastle College of Science.

SCIENTIFIC SERIALS.

L'Anthropologie, tome iv. No. 3.—The current number contains four papers of much interest. Dr. R. Collignon contributes an article on the proportions of the trunk among the French, whom he divides into three classes: (1) the Celts, in the sense in which Broca used that term, that is to say, a short, dark, brachycephalic and mesorhine people, such as those found in Auvergne, Limosin, and the centre of France generally; (2) the tall, fair, dolichocephalic Kymris, found in the north-eastern or Belgic departments of France; and (3) those who are really cross-breeds. The measures of the trunk are five in number:—(1) The total height, in the sitting position, from the interclavicular notch to the seat; (2) the maximum bi-acromial diameter; (3) the maximum bi-humeral diameter; (4) the maximum bi-iliac diameter; (5) the maximum bi-trochanteric diameter. The following measures of the thorax are also taken: (1) the distance from the superior border of the clavicle to the inferior border of the false ribs, measured on a perpendicular line passing over the nipple; (2) the transverse width, and (3) the antero-posterior width, at the height of the nipples; (4) the circumference just below the nipples; (5) the circumference about 3 c.m. below the nipples. Observations were made on sixty Celts, seventy Kymris, and eighty Celto-Kymris. It appears that there is a regular gradation between the three classes. Among the brachycephalic Celts, the trunk and thorax are shorter than amongst the dolichocephalic Kymri, whereas in all other respects the measurements of the Celt exceed those of the Kymri. The people of mixed blood occupy an intermediate position. When the total height or the length of the

trunk is taken as a standard, the same general results are obtained, but the length of the thorax as compared with that of the trunk is greater in the Celts than in the Kymri. A comparison with similar measurements of various races of Tunis, negroes of the Soudan, and a single bushman, leads the author to the conclusion that in any given race all the measures of the body increase in absolute length and diminish in relative length as the stature increases, and *vice versâ*.—In a paper on the Matriarchate in the Caucasus, Maxime Kovalevsky adduces facts which tend to prove that the ancestors of the mountaineers who live in the high valleys of the Caucasus at the present time practised what Morgan and Fison have called "group marriage."—Dr. H. Ten Kate gives an account of his researches in Malaysia and Polynesia during a scientific mission promoted by the Royal Geographical Society of the Netherlands, in the course of which he examined 999 Malaysians of different races, and 314 Polynesians. The predominant colour of the skin among the Malaysians is brown and dark brown, while among the Polynesians it is light brown and yellow. The Malaysians have generally wavy or curly hair, but straight hair is a characteristic of the Polynesians. The Malaysians are mesocephalic; the Polynesians brachycephalic. Among the Malaysians the nose is concave or *retroussé*, while the Polynesian noses are straight and aquiline in about equal proportions. As regards stature, the Malaysians are below middle height and the Polynesians tall.—Dr. P. Topinard gives an interesting account of Anthropology in the United States, where the subject has received so much attention during the last few years. The question of the antiquity of man in North America is discussed at some length, and the general conclusion arrived at is that it does not exceed 15,000 years. Dr. Topinard proposes to continue the examination of American questions in future numbers of *L'Anthropologie*.

Bulletin de l'Académie des Sciences de St. Pétersbourg, New Series, vol. iii. No. 3.—Preliminary report on the results of the archæological expedition to the Orkhon River, by W. Radloff. The ruins of Khara-Calgasun, the old city of the Uigurs, close by which lie the ruins of a palace of the Mongol Khans, have been explored, as also the Tükie monuments in the valley of Tsaidamin-nor. In the monastery of Erdeni-dsu, about 27 miles south-east of Kosho-tsaidam, and 20 miles south of Kharabalgasun, the expedition has discovered several stones, covered with Mongolian, Tibetan, and Persian inscriptions which, in Prof. Radloff's opinion, prove that the old town of Karakorum stood at this spot. This position would agree with the Chinese indications which give to Karakorum a position of 100 *li* south of Ughei-nor. Many maps, plans, photographs, and casts of inscriptions have been brought in by the expedition.—Reports of MM. Clements, Dudin, Yadrintseff, and Lewin, relative to the same expedition.—Photographic spectrum of Nova Aurigæ, 1892, observed at Pulkova, by A. Belopolsky. Full details of the observations and measurements made on the photographs are given. In his conclusions the author considers an eruption of the star as not probable, and concludes in favour of a superposition of the spectra of two or more bodies in the spectrum of the Nova.—On a group of peculiar rocks brought from the Taimyr-Land by A. Middendorff, by Dr. K. Chrustschoff.—On a new species, *Felis pallida*, from China, by Eug. Büchner. The species is near to *Felis chaus*, Güld., but partially differs in coloration, as also in the length of the tail. The specimens described were brought in by Przewalski in 1884 from the south Tetung ridge in Gan-su.—On the state of the basin of the Black Sea during the Pliocene Age, by N. Andrusoff. The following conclusions are arrived at: The now deep part of the Black Sea remained submerged since the Sarmatian epoch, and was covered with brackish lakes of the Caspian type; however, it was separated from the Mediterranean by a continent which occupied the place of the Archipelago and the Ægean Sea. This continent was submerged, and a communication between the Mediterranean and the Black Sea was established at a very recent epoch, when the Black Sea already had its present shape.—On the differential equation of Lamé-Hermite, by F. Brioschi.—On the Perseids observed in Russia in 1892, by Th. Bredikhin. Observations, with the view of determining the decrease of the inclination of the orbits of the meteors, in proportion to the time-interval from August 10·5, have been made throughout the duration of the shower at Moscow, Pulkova, and a place in the district of Kineshma. All observations, including 339 meteors, are embodied in seven lists, or charts, published in full. The radiant has been deduced from each chart separately, and given for eight different dates, from July 29 to August 29. The surface of radiation has a circular form, its diameter having a length of nearly 45°, and the radiant point really suffered displacement.—On the embryonal development of the birch, preliminary communication, by S. Nawaschin. It has two phases in common with the development of the Casuarinæ, which therefore cannot be separated from other Angiosperms. They are evidently connected, through the birch, with the lower Angiosperms (Apetales).—On the representation of the daily change in the temperature of the air by means of Bessel's interpolation formula, by H. Wild. Critics of conclusions, opposed to those of the author, and arrived at by Dr. Paul Schreiber, director of the Chemnitz Meteorological Institute.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 18.—Henry John Elwes, President, in the chair.—Mr. R. Adkin exhibited two *Leucania vitellina* and one *L. extranea*, taken in the Scilly Islands, in August 1893.—Mr. R. South exhibited a specimen of *Polyommatus bœticus*, and a number of varieties of *Chrysophanus phlœas*, captured in Kent, in September last, by Mr. Sabine; also a curious variety of *Argynnis euphrosyne*, taken in Lancashire in May 1893; a pallid variety of *Vanessa urticæ*, taken in Monmouthshire, in July 1893; and a *Triphæna pronuba*, the right wings of which were typical, and the left wings resembled the variety *innuba*, caught at sugar, in Dovedale, Derbyshire, in July 1893.—Mr. G. H. Verrall exhibited a specimen of the Tsetse (*Glossina morsitans*), and also one of the common European allied species (*Stomoxys calcitrans*). He also exhibited a specimen of *Hæmatobia serrata*, Dsv., which he stated was not uncommon on cattle in England, but believed to be harmless; while in North America the dreaded "horn-fly" is said to be the same species.—Mr. Elwes exhibited a larva which he had found three days previously under stones on a moraine, apparently quite destitute of vegetation, in the Austrian Tyrol, at an elevation of about 7000 feet. He remarked on the number of Alpine butterflies, some of them in fresh condition, which he had seen whilst chamois-hunting in the Austrian Tyrol during the last week, and he suggested that in such a fine autumn as the present one collectors might find more novelties among the larvæ of Alpine species than in the summer.—Col. Swinhoe read a paper entitled "A List of the Lepidoptera of the Khasia Hills" (pt. 2). The President said he thought all entomologists would be grateful to Col. Swinhoe, Mr. Hampson, Mr. Meyrick, and others for the work they had recently been doing in describing the moths of India; but as the district of the Khasia Hills was probably richer in species than any other part of India, except Sikkim, and new species were being received almost daily, it was impossible to make any list complete. Mr. Jacoby, Mr. McLachlan, Mr. Jenner Weir, and Col. Swinhoe continued the discussion.—Mr. E. Meyrick communicated a paper entitled "On a Collection of Lepidoptera from Upper Burma." The author stated that the species enumerated in the paper were collected by Surgeon-Captain Manders whilst on active service in the Shan States and their neighbourhood, shortly after the British annexation of the territory. A discussion followed, in which the President, Surgeon-Captain Manders, and Col. Swinhoe took part.

PARIS.

Academy of Sciences, October 23.—M. de Lacaze-Duthiers in the chair.—Observations of Brooks' Comet (1893, October 16), made at the great equatorial of the Bordeaux Observatory, by MM. G. Rayet and L. Picard.—On the movements of the surface of the heart, by M. Potain. The object of this investigation was to obtain the interpretation of the cardio-pulmonary sounds resulting from the movements communicated to the lung by the heart, and the local inspiration phenomena produced by these movements. The movements were recorded by an instrument capable of tracing simultaneously at several points of the surface the displacements in all directions. From these traces the actual trajectories of the points were constructed, the points being five taken on the accessible surface of the ventricle of an animal with an open chest. The general movement thus indicated is, during systole, a rapid retreat of the surface and an equally rapid translation to the right; this is, in fact, the well-known torsional motion. At the end of the ventricle, the retreat is only effected towards the end of the systole. At the beginning

of diastole, the whole wall rapidly collapses; it then rises, slowly at first, as the blood gradually enters the ventricle, and then rapidly, when the systole of the auricle takes place. On comparing these trajectories with the sounds heard in man and sometimes also in animals, it is found that their amplitude is greatest where these sounds are most intense and frequent, that their direction is that calculated to produce upon the lung a rapid aspiration during systole, and that the rhythm of the sound is itself in correspondence with the variations of speed of the movement. The relation thus discovered solves a complex problem of auscultation.—Observations of the new comet Brooks (1893, October 16), made at the Paris Observatory (west equatorial), by M. G. Bigourdan.—On certain families of gauche cubics, by M. Lelieuvre.—On the kinetic interpretation of the function of dissipation, by M. Ladislas Natanson.—Determination of the velocity of propagation of an electric disturbance along a copper wire, by means of a method independent of any theory, by M. R. Blondlot.—Analysis of a vanadiferous oil, by M. A. Mourlot. This oil, of slight density varying between 1·15 and 1·20, is of a fatty appearance, and contains 51·52 per cent. of volatile matter. The percentage of hydrogen is much lower than that of the vanadiferous oil recently discovered in Argentina by Mr. Kyle, and carbon and nitrogen show a larger percentage. The most interesting feature of this oil is the presence, in the ashes, of a large proportion of vanadic acid in the shape of alkaline and metallic vanadates. It also occurs free in this oil, and may be extracted by washing with ammoniacal water. A quantitative analysis gave a percentage of 0·24 of vanadic acid in the oil, and 38·5 per cent. in the ashes. As the oil is abundant, some important applications of vanadium may be looked for if the properties of the metal are found to be commercially valuable.—On the perfume of the violet, by MM. Ferd. Tiemann and P. Krüger. This is an account of the success so far obtained in the analysis of the perfume-oil contained in the fresh flower of the violet or the dry root of the iris, and its synthesis from lemon-juice.—New synthesis of erythrite, and synthesis of an isomeric erythrite, by M. G. Griner.—Influence of organic solvents upon rotatory power, by M. P. Freundler.—On certain chemical conditions of the activity of brewers' yeast, by M. J. Effront. It was found by a series of experiments that various kinds of yeast, after treatment with gradually increasing quantities of ammonium fluoride, acquired a very considerable fermenting power, estimated at about ten times that developed before this treatment. It also imparted properties which some physiologists had up to now considered as the privilege of certain species.—On the propagation of the *Pourridié de la Vigne* by slips and graft-slips placed in sand "in stratification," by M. A. Prunet. The storage of grafting slips in moist sand for the next season encourages the growth of small fungi upon them, which give rise to a fatal disease of the vine.—On a dislocation in the shape of a mushroom in the Alps of Haute-Savoie, by M. Maurice Lugeon.—On a halo observed at Créteil, on October 22, 1893, by M. Georges Pouchet.

GÖTTINGEN.

Royal Society of Sciences.—The following papers of scientific interest appear in the *Nachrichten* of July to September 1893:—

July 26.—E. Ehlers: On the morphology of the Bryozoa. W. Nernst: Dielectric coefficients and chemical equilibrium. W. Holtz: On direct impressions of magnitude in artificially induced optical illusions. W. C. Röntgen: On the influence of pressure on the electric conductivity of electrolytes.

August 2.—O. Wallach: On compounds of the camphor series. W. Voigt: Observations on rigidity under homogeneous deformation. Also, on an apparently necessary extension of the theory of elasticity. W. Meyer: G. F. Grotefend's first announcement of his decipherment of the cuneiform character.

AMSTERDAM.

Academy of Sciences, September 30.—Prof. van de Sande Bakhuysen in the chair.—Mr. Bakhuis Roozeboom described the method for the determination of oxygen dissolved in water studied by Dr. Romyn. This method unites simplicity and accuracy, and can be executed outside the laboratory. Its use in hygiene was indicated by two series of researches, the first aiming at the determination of the quantity of pure water necessary to improve that of the canals of Leyden, whilst the other concerned the analysis of the oxygen in different parts of the water-conducts in Arnhem, in view of the corrosion of the iron tubes.—Prof. Schoute treated on sections and projections of tessaract and hexadecatessaract.—Prof. Korteweg dealt with the classification of the curves of the third class or the third order, and a graphical representation of the totality of these curves and their division in three tribes by the points of a plane, every point representing all the projective and reciprocal transformations of the same curve.

Netherland Zoological Society, September 30.—M. Hubrecht in the chair.—M. van Wyhe contributed a paper on the ventral nerves (ventral roots) of Amphioxus. With the help of Golgi's method the author was able to state that the ventral nerves are furnished with true terminal organs, Retzius not having succeeded to observe them. The author then discussed the question as to why the ventral part of the motor nerves lies within the myotome, and not, as with the dorsal part is the case, at its medial side. Finally, the same author pointed out that in Amphioxus the ventral nerves contain sensory nerves also.—M. J. T. Oudemans exhibited specimens of *Alytes obstetricans*, taken by him for the first time in the Netherlands, viz. near Valkenburg (Limburg).—M. Horst exhibited a new gigantic European earthworm, obtained near Arcachon (France), and which he referred to a new species (*Allolobophora Savignyi*). The same author observed the larva of a dipterous insect within the mouth of a Perichæta from Java.—M. Hoek made remarks on the spawning of the Anchovy in the Zuiderzee. Another communication from the same author contained an account of trawling experiments in the North Sea.

THURSDAY, NOVEMBER 9, 1893.

DR. WERNER VON SIEMENS.

Personal Recollections of Werner von Siemens. Translated by W. C. Coupland. (Asher and Co., 1893.)

WERNER VON SIEMENS was a representative man of this nineteenth century, the century in which "the art of directing the great sources of power in nature for the use and convenience of man" has been more studied and applied than in any other, we were almost saying than in all others. And no other century has produced quite such a man—a man in whom the ability to apprehend the secrets of nature was united with the ability to apply them to industrial purposes. Many circumstances combined to favour him, both of a personal and public character. His father was evidently a man of strong common sense; his mother was refined in her tastes, cultured in her mind, and devoted to her children. The children were fortunate in having such parents to guide and watch over them. At that time, as now, first-rate schools and colleges existed throughout what now forms the German Empire, and in these a good mathematical and scientific education was to be obtained, which was taken advantage of by the Siemenses, both as boys and young men. Another matter which was specially favourable to Werner Siemens was his military training; regular drill, strict discipline, endurance, and implicit obedience, learnt and practised in his own person, helped to make a man of him. Besides this, these young men were born just at the right time, if we may say so, to take advantage of the recent discoveries in, and formulation of the principles of, the natural sciences of heat and electricity and magnetism. These sciences were at that period in the active, nascent state. Galvani and Volta, Gauss and Weber, Oersted and Faraday had set the world wondering, and themselves, the philosophers, thinking, analysing, and systematising, and the men of imaginative minds, the poets of industry, inventing. Great discoveries had been made in former days, but these were in the realms of the Cosmos; they were not suitable for application to the daily uses of men, and were not, as those were, startling and impressive.

One of the first applications of electricity was to electro-plating, the covering of the baser metals with a thin layer—almost a film—of the nobler metals. And when in 1842 Werner Siemens applied for and obtained a Prussian patent, no process of galvanic gilding or silvering was known in Germany. He tells us that he had experimented with all the gold and silver salts known to him, and besides the hyposulphites had also found the cyanides suitable. The use of the latter had been made and patented by the Messrs. Elkington of Birmingham, so that a patent was only granted to Werner Siemens for the former. His brother William was despatched to England, where he took out a patent which he succeeded in selling to the Messrs. Elkington for £1500, and this money helped the young men on their road to independence and fame.

Whether it is that the minds of those engaged on the problems connected with the application of the forces of nature to industrial purposes are necessarily turned towards the measurement and regulation of these forces, we would not say, but meters and governors seem to have a special fascination for them. And so it was with these men. The problem of the regulation of the steam-engine seems to have proposed itself to the mind of William; both brothers, however, were engaged in its solution, and the differential regulator or chronometric governor was the result.

In the work we are reviewing there are few dates, but fortunately Dr. Pole's "Life of Sir William Siemens," and the scientific and technical papers of the brothers themselves, already published by Mr. John Murray, supply these. Quoting then from a paper by C. William Siemens on the progress of the electric telegraph, we find that "in the year 1845, when the practical utility of electric telegraphs had been demonstrated in England, several continental governments had determined upon their establishment." A Royal commission was appointed in Prussia, of which Dr. Werner was the most active member. They favoured an underground system, and charged him to institute experiments.

Here we stand on the threshold leading to, and opening up on, one of the greatest achievements of modern days. The underground system was only a stepping-stone to submarine telegraphy, and was not in itself a permanent although a temporary success. But there in Germany just at this time something was wanted, and here in England it existed; and these two brothers—the elder there, the younger here—were the means of completing the circuit. In the winter of 1844-45, "I recollect well seeing the first specimen of gutta-percha exhibited at the Society of Arts, I think by Mr. Montgomerie. . . . He was kind enough to give me a piece, which I forwarded to my brother, Dr. Werner Siemens. . . . I sent him this piece of gutta-percha in order that he might try whether it was not superior to india-rubber for insulation purposes. He did so, and after some time, having procured for him at his request a further supply, he made experiments, and in the course of about twelve months he proposed to the Prussian Government the use of gutta-percha for insulating telegraphic land wire." Dr. Werner constructed a screw press, by which the heated gutta-percha was cohesively pressed round the copper wire under the application of high pressure; this was well insulated, and permanently retained its insulation. And so, just at the time that it was wanted, a substance hitherto unknown came to light!

In the summer of 1847 the first long subterranean wire from Berlin to Grossbeeren was laid, and the telegraph commission had under consideration the employment "both of the wires coated with gutta-percha by pressing, and also of my dial and printing telegraph in the telegraph system about to be introduced into Prussia." On October 12, 1847, the factory of Siemens and Halske was started, but Dr. Werner still retained his military commission. In June, 1849, he requested his discharge from the military service, and soon after also resigned his office as technical manager of the Prussian State telegraphs.

We are not attempting in any detail to survey the whole field of Dr. Werner von Siemens's activity; we are

simply drawing attention to the most prominent landmarks, which may be used as points from which to carry out the triangulation, and as stations on which to set up the necessary delicate instruments of observation. Dr. Werner von Siemens was a remarkable man; he had a most successful career; he left indelible marks on the progress, both scientific and industrial, of his day, and there are lessons to be learnt from his work, and from his systems and methods.

Let us rest here a moment. This factory was just the very thing that was required at the time. The two members of the firm were—the one, Dr. Werner Siemens, a man possessing clear scientific views of natural forces and phenomena, and an inventive mind; the other, Mr. Halske, a man thoroughly acquainted with mechanics, the use of machines and tools, and possessing the skill to make, and to teach others how to make, delicate mechanism. There was a demand in Germany, in Russia, in England, and elsewhere, for what they could make; their work was thoroughly to be relied upon, and orders streamed in on them.

Dr. Siemens says somewhere in this volume that everything he has done for natural science has been due to a claim made upon him by applied science. It was the absolute necessity under which he was to make accurate measurements that set him to work to invent an exact standard of resistance, possessing which he was afterwards able to elaborate a rational method for testing the electrical condition of submarine cables. Previously to this, Jacobi's standard, which was a determined length of copper wire of a determined section, was used at the Berlin factory, but copies of these standards were found to differ so much that Dr. von Siemens set to work to introduce a standard of his own. In revolving this matter in his mind he came to the conclusion that "it was both desirable and convenient to be able to combine a definite geometrical notion with the unit of resistance." He therefore used mercury, the only metal fluid at ordinary temperatures, whose resistance cannot be affected by molecular variations, made a series of important experiments, and finally having defined his unit as a metre length of mercury of a square millimetre section at 0° C., he sent copies of his standard to physicists and telegraph engineers suggesting their use in determinations of resistance. We refrain from entering into a discussion as to the relative values of units, whether Weber's absolute unit, the B.A. c.g.s. unit, the ohm, or others; the main point is that Dr. von Siemens wanted a clearly defined unit, he had found the absolute necessity for it in his electrical work, and now possessing it he was able to press forward to other achievements. Here was a decided step in advance. Measurements which had previously been variable were now uniform, tests which formerly could not have been made could now be applied, and work which was formerly carried on more or less by rule-of-thumb, could now be done with a certainty of result.

We have referred to submarine telegraphy as one of the great achievements of this century, and the brothers Siemens, Werner, William and Carl, have taken a share in it. Almost every submarine cable of importance has been shipped from the Thames. The first tentative efforts were made in England, and the final successful results have been achieved here. Cable-laying is now one of the scientific arts, and our author has had a large share in making it so.

We are here brought face to face with the two sides of the question, the scientific and the technical, and at the same time with two national characteristics, the combination of which has produced these results: English enterprise, German investigation. And there is yet another link in this chain of events, which it is difficult to see how we could have done without, the finally unsuccessful but at the time needful and useful practical experiment of underground cables in Prussia. "My friend Halske" . . . "was the first to encounter these phenomena." "Halske found, first of all, that with shorter lines our self-interrupting indicator telegraphs acted with much greater speed than corresponded to the resistance of the line. When communication between Berlin and Cöthen had been established, a distance of about 95 English miles, the giving apparatus ran with double velocity, whilst the receiving apparatus stopped altogether. This at the time inexplicable phenomenon occurred the earlier the better the lines were insulated, which induced Halske purposely to impair the insulation of the line by the addition of artificial watery by-passes." "When the underground line had been extended to Erfurt, Halske's watery by-passes were no longer sufficient. But meanwhile I had become convinced that the peculiar behaviour of the underground wires could only be ascribed to the electrostatic charge already observed at the testings in the factory, the wire namely forming the inner, the damp soil the outer coating of a Leyden jar." "The very surprising and disturbing phenomena of electrical charges in underground conductors required thorough study. Further, it was necessary to establish a system for the determination of the situation of faults in the conduction and insulation of underground wires by measuring currents at the end of the wires. The uncertainty of the measurements of currents led to the necessity of replacing them by resistance measurements, and thereby to the setting up of fixed reproducible standards of resistance and scales of resistance. For this purpose the methods and instruments for current and resistance measurements had also to be improved and adapted for technical use; in short, a whole series of scientific problems had cropped up, the solution of which was called for by technical needs."

And so later on, when the actual problems of submarine telegraphy had to be solved, Dr. Werner took his share in their solution all the more ably because of the experience he had already gained, and of his system of studying the science on which the art was founded. His narrative, especially in this connection, is full of adventures, not unaccompanied with danger, the description of which is always interesting and often graphic.

The lesson of the life, of which a few personal recollections are given in this volume, appears to be this: Find out the work you were sent here to do, and do it with your might. All the work that has to be done is not great work, but may be good work for all that; it may not lead to honour and fortune; but it has to be done, and if you are the one who has to do it, do it well.

Dr. von Siemens had a work to do; it matters little, it seems to us, whether others were engaged on the same work or not; he did his share. As to who the person is

that first made a particular discovery is often a difficult question to settle ; it is, after all, perhaps a matter of accident, or shall we say rather a matter of gift. But the man who follows his guiding star, and is led by it to honour, and success, and fortune, is one whose example others may well follow, even though it may not lead those others there. A great work or a very little work has to be done ; set to work and do it. There is your guiding star shining clear and bright ; follow it. There may be bright scintillations to the right and left ; they may be merely *ignes fatui*, or they may be other men's guiding stars ; they have nothing to do with you. You may have to work hard, but any way try to work wisely !

IRON ORES.

The Iron Ores of Great Britain and Ireland. By J. D. Kendall, F.G.S. With numerous illustrations. (London : Crosby Lockwood and Son, 1893.)

ALTHOUGH numerous works relating to mineral deposits of particular districts have appeared at different times, besides larger treatises dealing with the subject generally, such as the late John Arthur Phillips' "Ore Deposits," the want of a systematic account of our present knowledge of the origin and occurrence of British iron ores, and of the means of working these ores, has long been noticed. This want will be supplied by the volume under consideration. The author is a mining engineer of thirty years' experience, and he has been able to supplement a careful study of the available literature by unpublished information derived from his own observations. The result is a volume that will prove of substantial value as a work of reference to all interested in the iron industry of this country, more especially as the published information can only be found by a laborious search through the volumes of the Journal of the Iron and Steel Institute, and of the Transactions of other societies.

Mr. Kendall has broken up his volume, which covers 430 pages, into four parts. In the first, he gives some interesting information regarding the early working of iron ores, of which there is indirect evidence in nearly all the valleys of the Lake district. The presence of Roman coins, some of them as early as Trajan, found in heaps of iron cinder in Sussex and near Monmouth, proves that iron was made at a very early period from the red and brown oxides. Indeed, it is possible that these beds were worked at an even earlier period, for flint flakes and rough unturned pottery were found by Boyd Dawkins on the surface of a slag heap near Battle. In the second part, the author discusses the geological position and mineralogical characteristics of iron ore deposits. The third section deals with the age and origin of the deposits, and the last describes the method of searching for and working iron ores, with useful information on working costs, selling prices, and conditions of leases.

The author's task is not a light one. Within the limits of 430 pages to describe even the main features of the long list of mines which give the United Kingdom (1891) its 12,777,689 tons of iron ore, valued at £3,355,860 at the pit's mouth, is by no means easy. With the aid of forty-one illustrations and five folding plates, he has, however, been enabled to compress a large amount of information within a comparatively small compass, the value of the descriptions being increased by the insertion of bibliographies for each district.

As would naturally be expected, all the ores noticed in the volume are not treated with equal fulness, preference having been given to those of the greatest commercial or scientific importance. It is to be regretted that the great lode of Perran, near Truro, should have been dismissed in a single line. The late Sir Warington Smyth made many attempts to introduce this curious deposit to the notice of ironmasters, and it has formed the subject of numerous important memoirs. The most interesting descriptions given by Mr. Kendall are perhaps those relating to the district with which he is specially acquainted —the hæmatite district of West Cumberland and Furness, a district which has received less attention from geologists than any other of equal importance in the British Isles. The ores are of special value for the part which they play in admixture with the poorer qualities of ironstone, as well as for the production of Bessemer pig-iron. So irregular, however, are these deposits that the boring-tool may easily pass within a few inches of a mass worth thousands of pounds without discovering a trace of it. There can be no doubt that the acquirement of an accurate practical knowledge of these irregular deposits, of which the surface tells no tale, is the most difficult subject with which the mining engineer has to deal, and yet in many cases the difficulty is entirely ignored, with the result that the cost of exploration is enormously increased.

The chapter on the ironstones of the carboniferous rocks contains little that is new, the bulk of the information being contained in the "Memoirs of the Geological Survey." The analyses given relate to the iron ores collected by S. H. Blackwell, and the author might with advantage have mentioned the fact. The formation of this collection marked an epoch in the history of metallurgy, for, notwithstanding the magnitude of the interests involved in the iron and steel industries, no systematic collection representing the workable ores of the kingdom had been made until the Great Exhibition of 1851. The want was then supplied by the liberal exertions of Mr. S. H. Blackwell, a Dudley ironmaster, who, after the exhibition, presented this extensive and interesting series to the Museum of Practical Geology, munificently placing a sum of £500 at the disposal of Dr. Percy towards defraying the cost of their analysis. The results were subsequently published at Government expense in the "Memoirs of the Geological Survey."

The perplexing and fascinating subject of the genesis of iron ore deposits is treated by the author with great fulness, and his conclusions deserve attentive consideration. He brings forward a large amount of evidence in support of the views propounded by Sorby and by Huddleston that the ores of Cleveland and Northamptonshire were produced by the replacement of an ordinary limestone, and extends the theory to all deposits occurring in the secondary rocks. The source of the iron, he believes, may have been in the clays, with which all these deposits are closely connected. In the case of the red hæmatites, he is of opinion that the most likely

source of the iron is to be found in volcanic emanations of ferric chloride, a theory that appears more ingenious than sound. The author does not appear to have consulted the writings of recent foreign workers in this field. A study of the memoirs of R. D. Irving, Kimball, Van Hise, and H. V. Winchell, on the genesis of American iron ores, might have induced him to modify some of his views.

The author's remarks on the value of geology to the mining engineer deserve attention. It is undoubtedly of urgent importance for the economical utilisation of the iron ore resources of the kingdom, that those entrusted with the management of mines should have a more extended knowledge of the nature of irregular deposits than is too often the case. In these days of technical education, it is surprising to see money wasted in searching for these deposits in situations where some knowledge of stratigraphy would have shown that there was no chance of finding them. It is surely not too much to ask that mineral explorers should understand the elements of their work. BENNETT H. BROUGH.

OUR BOOK SHELF.

The Shrubs of North-Eastern America. By Charles S. Newhall. 8vo, pp. 249, with 116 woodcut figures. (London: G. P. Putnam's Sons, 1893.)

THE author of the present volume had previously written a similar book on the trees of the same region, which he defines as "Canada and the United States east of the Mississippi and north of the latitude of Southern Pennsylvania." This region is peculiarly rich in both trees and shrubs, most of which are hardy and will flourish in this country; and, as a matter of fact, many are familiar here in cultivation. Therefore a work of this kind appeals to amateurs on this side of the Atlantic as well as the other, and, although an unpretentious production, we can recommend it as a useful aid to those interested in the subject, especially to such as already possess some general knowledge of shrubs. The descriptive part is as free from technicalities as it could well be, and intelligible to any person whose knowledge of botany does not go beyond the veriest rudiments. The figures are for the greater part merely outlines, and so far accurate; yet hardly sufficiently detailed for use in our gardens, where American plants are associated with those of all other temperate climes. In the fields and forests of America they would be more serviceable. Botanical and popular names are given, and the derivation of the former, at least as to genera. The descriptive matter is here and there enlivened by appropriate poetical quotations; and the properties and uses of the more important plants are given. The Ericaceæ are perhaps the most numerous and attractive among the shrubs of Eastern America. No fewer than ten genera of this family are enumerated. Missing the Rose Acacia, *Robinia hispida*, we had almost convicted the author of omitting a favourite shrub; but we find it does not reach quite so high a latitude as 40° in America, though it is quite hardy in most parts of the British Islands. We also missed the *Menispermum*, *Wistaria*, and other climbers; but we suppose they will be included in the "Vines" of North America, to be dealt with in a third volume, announced by the author. W. B. H.

Mensuration of the Simpler Figures. (Univ. Corr. Tutorial Series.) By William Briggs and T. W. Edmondson. (London: Clive Univ. Coll. Press, 1893.)

THOSE students who have acquired a fair knowledge of algebra, trigonometry, and Euclid, will find in this book a most excellent guide to the mensuration of most of the more simple figures generally met with. Instead of presenting the reader with the stereotyped "rule and example" system, the authors have treated them as just a series of problems giving proofs of the formulæ used and numerous examples. That the book throughout is clearly and yet not too fully written speaks well for the student, and its scope is intended to meet the requirements of candidates for such examinations as the Intermediate B.A. and B.Sc. of the University of London. The measurement of rectilinear figures and the circle are first treated, followed by chapters on the geometry of the rectilinear solids and their surface-areas. This is succeeded by the methods of measuring the volumes of the rectilinear solids, and the last two chapters deal conclusively with the cylinder and cone and the sphere. The definitions throughout are well expressed, and the problems neatly worked out, while the figures could hardly be improved. We may mention that in the chapters relating to the rectilinear solids all figures have been drawn in perspective and shaded, giving the student a clearer idea of the forms of the various figures.

The Discovery of Australia. By Albert F. Calvert (London: George Philip and Son, 1893.)

MR. CALVERT describes his book as "a simple statement of such historical facts as I could collect; and a reproduction of certain maps which more or less illustrate the gradual progress of knowledge regarding the great island continent, now called Australia." From this it will be inferred that there is nothing strikingly novel in the production. Mr. Calvert has found many tracings on old charts indicating a knowledge of the existence of a great southern continent, and he thinks that probably some individual navigator landed on the western coast of Australia in the fifteenth or sixteenth century, afterwards bringing the news of his discovery to Europe. A large portion of the book is devoted to the voyages of Capt. Cook, the reason being that "he was really the discoverer of Australia in its present geographical configuration." The volume is well printed, and the maps are finely reproduced. It is doubtful, however, whether the author has added much to elucidate the subject which he treats.

Graphic Arithmetic and Statics. By J. J. Prince. (London: Thomas Murby, 1893.)

IN addition to questions in Practical Geometry, the Science and Art Department has given notice that in the future questions in Graphic Arithmetic and Statics will be included. The issue of this small book is intended to supply students with information on these two subjects, sufficient for both the elementary and advanced stages. In forty-eight pages the author has brought together all the important problems, working them out clearly for beginners with the help of diagrams. In addition to those of the more elementary kind, a graphical determination of the square roots of numbers, the resolution of forces, resultant of parallel forces, &c., are also dealt with. Nothing that the reader will find in this book will be found superfluous, though it could with advantage be slightly extended.

The Orchid Seekers. By Ashmore Russan and Frederick Boyle. (London: Chapman and Hall, 1893.)

UP the Sarawak river to Kuching, and thence to Sirambau, went a small party in search of a blue orchid reported to exist in that region, and supposed to be *Vanda cærulea* or *V. cærulescens.* The leader of the party was a German botanist well versed in orchidology, who identified each plant as it was found, and delivered botanical discourses whenever an opportunity occurred. The story

is mainly one of adventure; nevertheless, much of scientific interest is weaved into it, and the boy who reads it without skipping the closely-printed portions will obtain some useful knowledge of the natural history of Borneo.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Human and Comparative Anatomy at Oxford.

I AM sorry that Prof. Burdon Sanderson should state that a "misstatement" occurs in the article written by me in your issue of October 26, and still more so that whilst making such a charge he altogether omits to cite the "misstatement" which he sets out to correct.

My knowledge both of the University of Oxford and of the teaching of anatomy is, as a mere result of individual history, far more intimate than is that of my colleague, Prof. Sanderson, a fact which may account for some difference in our opinions on these topics.

When in 1885 the Convocation of the University was asked to sanction the payment of a small salary for a limited period to a lecturer in Human Anatomy—out of University funds already taxed to an inconvenient extent—there existed four ancient foundations in Oxford assigned to the support of teachers of "Anatomy," viz.: the Linacre Professorship of Human and Comparative Anatomy, the Tomlinsian Lectureship of Anatomy, the Aldrichian Professorship of Anatomy, and the Lee's Readership in Anatomy. The small Tomlinsian and Aldrichian endowments had been united in 1803 by Parliamentary authority, and the salary arising from them was in 1858 assigned to the payment of a demonstrator or demonstrators nominated by the Linacre Professor. There were thus, as teachers of anatomy in the University, the Linacre Professor and his Aldrichian demonstrator, and the Lee's Reader. Whatever may have been the conceptions of the ancient founders as to the nature of that study which they designated "Anatomia," or the intentions of University Commissioners who gave the title of "Professorship of Human and Comparative Anatomy" to Linacre's revived readership in medicine, or by whatever conditions the result may have been determined, it is certain that in 1885 the holders of the Linacre, Aldrichian, and Lee's teacherships were not giving that "technical training in anthropotomy," that "topographical knowledge of the human body," which forms a part of medical professional education, and is administered in every hospital-medical school throughout the country. What these Oxford teachers were doing was to teach anatomy in its broad academical sense. They taught the anatomy of man and of animals as a branch of biological science, and I venture to assert that they taught the anatomy of man and of vertebrate animals with as ample material illustration, and in as complete and detailed a way, as is desirable for the training of University students intending to pursue the study of any one of the great branches of biology *as a science*. What they did *not* do was to furnish the *professional medical* student with that special acquaintance with the arrangements of tendons, nerves, and blood-vessels in each little tract of the human body which might be the seat of a surgical operation or a medical exploration.

Both the teaching and the acquirement of these details is tedious and uninteresting, although necessary for the surgeon. The subject-matter is called "human anatomy," or the "anatomy of man"—as distinguished from "anatomy" in its wider sense, and more especially as distinguished from comparative anatomy. Human anatomy is not a branch of science; it is topographical information. In order to render it less uninteresting than it would be (and under some teachers is) when strictly taught, it is customary for the teacher of human anatomy to introduce scraps of the various branches of science which bear upon the significance of animal structure into his text-books and lectures. He thus imports a little physiology and mechanics, a little comparative anatomy or animal morphology and embryology into his teaching. The real significance, however, of the facts learnt by the medical student in his course of "human anatomy" is in their application to surgical and medical practice, and it is in referring to these applications that the teacher of human anatomy finds the legitimate and most successful leaven for his dead weight of detail.

Such being the somewhat repellent character of the pursuit of human anatomy considered apart from the science of morphology or comparative anatomy, it is not surprising that the Oxford teachers of "anatomy" in 1885 had all devoted themselves to the latter study, and left the technical topographical human anatomy uncared for.

But unattractive and uninteresting as it is, this human anatomy has to be "gone through" by the medical student. Oxford had been roused to a sense of her obligations to medical study by a movement, in which I took a somewhat prominent part, and accordingly when in 1885 it was represented to Convocation that although the University had three teacherships of anatomy and splendid collections illustrating the structure of animals (including man), yet there was no provision for carrying on the instruction in anthropotomy necessary for technical students of medicine, that body generously and deliberately consented to provide a new teachership for the specific purpose of filling this gap in the machinery of the Oxford Medical School.

I should be very sorry to see any tendency to frustrate the excellent purpose of Convocation, and I feel confident that the renewal of the periodic grant made by that body to pay the salary of a lecturer in human anatomy must depend on the lectureship being strictly restrained within its original boundaries. We do not want at Oxford a fifth teachership of anatomy added to the four which have somehow slipped away from "anthropotomy" into pleasanter and more philosophic regions. The University ought not to be asked for more money with the object of effecting once more such a transformation. But this will certainly be the case if vague theories about "the academical teaching of human anatomy" are allowed to pass without protest.

Oxford, November 4. E. RAY LANKESTER.

P.S. It is strange that Prof. Sanderson (himself an Edinburgh man) speaks in his letter of the University professor of *Human Anatomy* in Edinburgh. There is no such professorship in Edinburgh. Sir William Turner is professor of *Anatomy* in Edinburgh, as is the eminent comparative anatomist Gegenbaur in Heidelberg. The separation of human anatomy from comparative anatomy has not been carried out in these Universities as it has been deliberately in Oxford. Anthropotomy is taught in the former by demonstrators and assistants acting under the direction of the professor of anatomy. That was the intention of the late University Commissioners with regard to Oxford when they constituted the Linacre Professorship of Human and Comparative Anatomy. Some persons, however, thought it best (I am not now discussing the merits of the arrangement) that the example of Edinburgh, Heidelberg, and other European Universities, should be departed from in Oxford, and that the functions of the Edinburgh Professor of Anatomy and his staff should in Oxford be divided between the Linacre Professor of Comparative Anatomy and an independent lecturer in Human Anatomy.

The Monros, Goodsir, Allen Thomson, and other distinguished Scotch teachers were, like Gegenbaur, Kölliker, and others in German Universities, professors of "Anatomy," not exclusively of "Human Anatomy."

The Oxford plan of relieving the titular Professor of Human and Comparative Anatomy of an important but technical branch of his teaching, by the appointment of a lecturer *ad hoc*, has not a precise parallel in other Universities. Moreover, in Germany the subject of microscopic anatomy or histology is very usually undertaken by the Professor of Anatomy (*e.g.* Kölliker, Waldeyer, His), although in Oxford the Professor of Physiology is by statute called upon to give instruction in histology. It would probably not meet with unanimous approval were the present Oxford lectureship in Human Anatomy—in imitation of "academical teaching" elsewhere—to be diverted wholly or partly to the subject of histology.—E. R. L.

"Geology in Nubibus." An Appeal to Dr. Wallace and others.

IN his timely and important letter to you, Dr. Wallace congratulated us all on having got rid of a *real* glacial nightmare by sweeping away the tropical glaciation which has been favoured

by some high authorities, including himself, Mr. Darwin, and Mr. James Geikie. While we may all share in this congratulation, it must be remembered what it involves.

It has been the fashion with an extreme and aggressive school of glacialists to postulate an excavating tendency in ice to which the formation of lake basins and valleys-without-outlets in mountain districts has been attributed. They will not allow that rock basins are due to any other cause than "omnipotent ice." They scoff at explorers of the mechanics of ice in Alpine countries, like Prof. Bonney and Mr. E. Hill. They jeer at those who have devoted much patience to unravelling the mysteries of Plutonic action, like Prof. Judd and others, who attribute a large number of lakes to dislocations and to foldings of the subjacent rocks. It is no use, in arguing with them, to refer to mechanical difficulties like those involved in conveying thrust of more than a certain amount through a substance like ice, which is known to crush under a moderate pressure, nor to produce any number of mechanical arguments against the capacity of ice to erode lake basins such as those in question; nor is it any use appealing to the stupendous geological difficulties against their conclusions which have been accumulated by quite a number of skilled geologists at home and abroad. All these efforts are futile, for we are told that the ice to which appeals must be made is quite a different thing to any ice we can experiment upon or examine, and that it must not therefore be measured by the ordinary laws that govern ice such as we know it, and this appeal to transcendental ice is considered to be orthodox science in the nineteenth century, an age when induction is supposed to have become a supreme law to us all, and when *à priori* postulates are generally discarded from the realm of physical research. Let this pass, however, and let us test the question in another way. Let us test it, in fact, by this very case of Brazil.

There has never been a glacial period in, nor are there traces of glacial action in the highlands of, Brazil, we are told by Dr. Wallace. Granted. How then can Dr. Wallace, and those who agree with him in this matter, explain the existence on the plateau of Bahia of perhaps the largest and most remarkable collection of rock basins in the world, rock basins existing, too, in close juxtaposition with most perfect examples of giants' cauldrons on the largest scale. This is assuredly a dilemma for the transcendental school of geologists.

Let me quote from Mr. Allen's graphic descriptions of these rock basins. Speaking of the plateau of Bahia, he says: "Over this whole region there is an almost entire absence of loose materials on the surface . . . slight knolls and shallow basins alternate which rarely differ more than 20 or 30 feet in elevation. In the rainy season many of these basins become filled with water, forming shallow lagoas varying in area from less than one to more than 50 acres, from most of which the water evaporates in the dry season . . . . So numerous were these lagoas for more than 50 miles that it seemed natural to speak of this region in my notes as the "Lake Plain." Almost everywhere the elevations are evenly rounded, indicating that the rocky crust has been exposed to rain and probably long continued abrasion. But the absence of abraded materials seemed most remarkable; very rarely were even loose boulders observed, though a few such were repeatedly noticed. At frequent intervals there were irregular holes in the rocks, usually nearly filled with water, to which the inhabitants give the name of 'caldeiraos.' These caldeiraos are of frequent occurrence. . . . . Nearly all of the considerable number examined proved to be genuine pot-holes, and some of them were of great size. The largest one I measured was elliptical in outline, 18 feet long, 9 or 10 in width, and 27 deep, with smoothly worn sides. . . . These pot-holes often occur out on the plain, far away from any high land, and they are sometimes found excavated on the summits of slight bulgings in the plain, or even on the top of a hill."

I would ask, in all seriousness, whether, if phenomena like these had been described from the Alps or from Nova Scotia, they would not assuredly have been pointed to by extreme glacialists as the unerring footprints of great ice-sheets, and yet Dr. Wallace, who is a champion of the school, repudiates the former glaciation of Brazil altogether.

What is to be said in regard to this dilemma then? It is quite clear that either the facts must be disputed (and who is to dispute them?), or else the champions of ice at-all-hazards must concede that rock basins and giants' cauldrons can be made by other agencies than ice. If so, they can be made as well in one place as in another. If they could be made by other causes on the plateau of Bahia, why not in the highlands of Tasmania?

I am bound to say I was taken aback by Dr. Wallace's comments on a letter from one of your correspondents, which appeared in NATURE a short time ago. That gentleman professed to make an exploration of certain parts of Tasmania with another experienced geologist. They were both champions of the glacial theory. They both went prepared to find traces of glacial action there, and certainly in our latitudes no evidence seems more easily discriminated, and they came back convinced that in the districts where the rock basins of Tasmania abound, there are no traces of glacial action to be seen. They could find none. Mr. Johnstone, who has written an elaborate and detailed geological memoir on the island, and who has explored it in many directions, could find none either, save on the western flanks and in the valleys of the Tasmanian Alps in the western part of the island, where it has been long known that traces of former local glaciers exist. There is absolute unanimity among the native geologists that nothing in the shape of ice-sheets existed there, and there is no ice-spoor in the central districts where the great Tasmanian lakes occur. Dr. Wallace's answer to all this was certainly unexpected. He has not himself visited the island, and yet he disputed not only the inferences but the facts and the observations. Why should the voice of Esau be listened to and approved in Brazil, and that of Jacob be repudiated in Tasmania? Mr. Johnstone and the other observers in Tasmania are assuredly to be trusted in such an issue quite as much as Prof. Branner. I cannot see on what ground the discrimination is made, except the desperate inconvenience of postulating a glacial nightmare in the tropics.

Assuredly the whole difficulty lies in championing a theory of the origin of lakes, unknown in geology until introduced by Ramsay, whose extravagance at times may be measured by some of his phrases addressed to the British Association when he presided over the geological section. From all sides there comes a revolt against this theory, which is based on no empirical evidence, and is at issue with the mechanical properties of ice so far as we know them, and with the observations of practised observers of the first rank. I am bound to say that those geologists who habitually make appeals to forces in Nature, and to properties of matter which are purely hypothetical and unwarranted by experience, are leading us back to times when Aristotle and deductive reasoning dominated European thought, and when Bacon had not yet taught us better things.

My attention has been called to an oversight in my previous letter. Among those who many years ago did good work in dissipating the particular glacial monster that was generated in the valley of the Amazons, was my old friend Dr. Woodward, whose papers on the subject in the volume of the *Ann. and Mag. of Nat. Hist.* for 1871, pp. 59 and 101, I had overlooked.

Henry H. Howorth.

30 Collingham Place, Cromwell Road, October 27.

Correlation of Solar and Magnetic Phenomena.

I was glad to see (NATURE, vol. xlix. p. 2) in the notice of Miss Clerke's "Popular History of Astronomy," that attention was drawn (1) to the correspondence in time between a certain luminous outburst seen on the sun on September 1, 1859, by Carrington and Hodgson, and a disturbance of the magnets at the Kew Observatory; and (2) to the statement of the late Mr. Whipple that the magnetic movement was really a small one, and that in his opinion the observed correspondence was a mere accidental coincidence. Those who have read Carrington's original account (Monthly Notices of the Royal Astronomical Society, vol. xx. p. 13) will remember that at the time he himself did not lean towards hastily connecting the phenomena, remarking that "one swallow does not make a summer." But authors of text-books on astronomy, who may be only to a partial extent observers, are too apt to state the matter in such a way as to give an impression that we have here an undoubted instance of direct connection, instead of a case of apparent connection, to be taken merely for what it is worth, seeing that the occurrence has remained to the present time without corroboration. I should like to take the opportunity to support, in the fullest manner, the opinion of Mr. Whipple, which acquaintance with the Greenwich magnetic registers tells me to be a true one. The magnetic movement in question, as recorded at Greenwich, was similarly small.

But the erroneous impression lives long. May I therefore be

further allowed to give some reasons for the opinion expressed. That there exists a relation between sun-spots and magnetism is undoubted. And although those who are able to study the variations of sun-spots side by side with the variations of magnetism can very well see to what extent the relation definitely holds, it is difficult adequately to convey to others a due impression of all the circumstances of the case. Periods of maximum sun-spots are periods of great magnetic activity and energy, whilst periods of minimum sun-spots are periods of magnetic quiet. But it has not yet been found possible to trace direct correspondence in details. Thus, when a large spot is present there may occur one or more considerable magnetic disturbances or storms, some enduring it may be for a few hours only, others it may be for several days, but, assuming direct solar influence, what it is that precisely determines when such disturbances shall arise is unknown. Further, at times of sun-spots being numerous, there is also considerable general magnetic irregularity. Now, in these magnetic disturbances and irregularities there will be innumerable individual motions far exceeding in magnitude that accompanying the Carrington sun outburst, and yet during all the many years that have elapsed since 1859, through which period the solar surface has been continuously scrutinised by hundreds of observers in different lands, no second occurrence similar to that of 1859 has come to light. But if there be so close a connection between solar and magnetic phenomena as the occurrence in question would seem to indicate, the fact that we have no corroboration of the solitary observation of 1859 is surely remarkable, considering that, of late years, it is very much to correspondence in details that attention has been to a great extent directed. If irregular magnetic movements were comparatively few, the observation of 1859 might possess some significance, but they are, on the contrary, multitudinous, many at times occurring during the course of a single day, and often of considerable magnitude, but yet without any recorded accompanying solar manifestation.

To sum up, the points of the matter may be thus stated :—

(1) The solar outburst in 1859 was seen independently by two observers : the fact of its occurrence seems therefore undoubted.

(2) The corresponding magnetic movement was small.

(3) Many greater magnetic movements have since occurred.

(4) No corresponding solar manifestation has been again seen, although the sun has since been so closely watched.

The solar outburst of 1859 would thus appear to have been a rare phenomenon, and its observed occurrence at the time of a recorded magnetic movement quite an accidental coincidence.

This conclusion in no way invalidates the question of general relation between sun-spots and magnetism, whatever may be the true explanation of that relation.

Greenwich, November 6. WILLIAM ELLIS.

The Recent Earthquake.

AFTER the Pembroke earthquakes of August 1892, you were good enough to insert a letter from me (vol. xlvi. p. 401) asking for observations from different places. In reply to this letter, I received so many and such valuable records, that I should be greatly obliged if you would allow me to make a similar request for accounts of the recent earthquake of November 2, in Wales and the West of England. I should be very grateful for descriptions from any place whatever. The questions printed below indicate the points on which information is chiefly desired, but if any observers are able and willing to give further details, I shall be pleased to send them my fuller list of questions, which I may remark are somewhat different from those given in the letter referred to above.

(1) Name of the place where the earthquake was observed.

(2) Time at which it was felt, if possible to the nearest minute.

(3) Nature of the shock. (*a*) Were two or more distinct shocks felt, separated by an interval of a few seconds? (*b*) If so, which was the stronger? (*c*) What was the duration (in seconds) of each, and of the interval between them? (*d*) During this interval was any tremulous motion felt or rumbling sound heard?

(4) Duration in seconds of the whole shock, not including the accompanying sound.

(5) Was the shock strong enough (*a*) to make doors, windows, fire-irons, &c., rattle ; (*b*) to cause the chair, &c., on which the observer was resting to be perceptibly raised or moved ; (*c*) to make chandeliers, pictures, &c. swing, or to stop clocks?

(6) (*a*) Was the shock accompanied by any unusual rumbling sound, and, if so, what did it resemble? (*b*) Did the beginning of the sound precede, coincide with, or follow the beginning of the shock, and by how many seconds? (*c*) Did the end of the sound precede, coincide with, or follow the end of the shock, and by how many seconds? (*d*) Were the strongest vibrations felt before, at, or after the instant when the sound was loudest, and by how many seconds? CHARLES DAVISON.

373 Gillott Road, Birmingham, November 6.

"An Ornithological Retrospect."

I HAVE been interested in reading "An Ornithological Retrospect," by your correspondent, Dr. Sharpe. His reference to myself by name in the concluding paragraph is partly my excuse for troubling you with a few remarks upon this article. Dr. Sharpe, in one long breath, deplores (pleonastically) the fact that "very little anatomical work has scarcely been done" recently in ornithology, and exults over a reviewer in a "leading London paper," who apparently took the same view—tomahawking him with the remark that "in every branch of the subject considerable progress has been made." I think that the opinion of the minority in this case is correct, and that our knowledge of bird anatomy is progressing. But those of us who are occupied with this study have frequently to regret the ignoring of anatomical facts by systematists ; this is particularly discouraging, since by far the larger proportion of papers upon bird anatomy are purely of systematic interest, dealing with the resemblances between bird and bird. Dr. Sharpe evidently feels that the British Museum Catalogues of Birds are not beyond criticism from this point of view. In one or two volumes there is a conspicuous absence of any arrangement in accordance with anatomical fact. Dr. Sharpe, therefore, is rather imprudently candid in saying that to understand these catalogues a man must be an ornithologist.

Zoological Society's Gardens. FRANK E. BEDDARD.

The Foam Theory of Protoplasm.

IN your issue of October 19 there appeared, under the title "Bütschli's Artificial Amœbæ," a review, by Dr. John Berry Haycraft, of Prof. Bütschli's work upon protoplasm. I venture to think that in many places Dr. Haycraft has misrepresented entirely Prof. Bütschli's researches, while other objections or criticisms which he brings forward are answered in the book itself. Since I have been engaged for some time upon a translation of Prof. Bütschli's work, which is now in the press, I must ask your readers to suspend their judgment until they have a better opportunity of forming an opinion for themselves.

2 Blackhall Road, Oxford. E. A. MINCHIN.

SCIENCE IN THE MAGAZINES.

AMONG the magazines received by us, the *Fortnightly* is well to the front as regards articles having a scientific interest. Dr. Alfred R. Wallace writes on "The Ice Age and its Work," with the object of explaining "the nature and amount of the converging evidence demonstrating the existence of enormous ice-sheets in the northern hemisphere, to serve as a basis for the discussion of the glacial origin of lake-basins, which will form the subject of another article." After briefly describing the foundation of the science dealing with glaciers and their action, and the early school of glacialists, Dr. Wallace states the phenomena which points to the former existence of glaciers in regions where the mountain-tops are at present below the snow-line. These are classified as follows :—(1) Moraines and drifts ; (2) Rounded, smoothed or planed rocks ; (3) Striæ, grooves, and furrows on rock-surfaces ; (4) Erratic and perched blocks. As a good example of a moraine, that in Cwm Glas, on the north side of Snowdon, is mentioned, together with those in Glen Isla (Forfarshire), and the Troutbeck alley near Windermere. In Cwm Glas, also, smoothed and rounded rocks are to be seen above the moraine. Striated, grooved, and fluted rocks are exemplified by those near the lakes of Llanberis, and by the remarkable effects exhibited at Kelly's Island, at the western end of Lake Erie. The enormous block near St. Petersburg, and the mass of Swedish red granite found at Fürstenwalde, south-east of Berlin, are given as in-

stances of erratic blocks. The erratic blocks from the higher Alps, which are found on the flanks of the Jura Mountains, are also shown to point conclusively to the former existence of glaciers stretching down the Rhone Valley as far as the Jura. The distribution of erratics in North America are next considered, and the crowning example of boulder transportation is said to be afforded by "the blocks of light grey gneiss discovered by Prof. Hitchcock on the summit of Mount Washington, over 6000 feet above sea-level, and identified with Bethlehem gneiss, whose nearest outcrop is at Jefferson, several miles to the north-west, and 3000 or 4000 feet lower than Mount Washington." After giving instances in Great Britain and Scandinavia of boulders carried above their source, Dr. Wallace says :—

We thus find clear and absolute demonstration of glacier ice moving up-hill and dragging with it rocks from lower levels to elevations varying from 200 to 2700 feet above their origin. In Switzerland we have proof of the same general fact in the terminal moraine of the northern branch of the Rhone glacier being about 200 feet higher than the Lake of Geneva, with very much higher intervening ground. As it is universally admitted that the glacier of the Rhone did extend to beyond Soleure, all the *à priori* objections to the various cases of rocks carried much higher than their origin, in America, the British Isles, and Scandinavia, fall to the ground. We must either deny the existence of the ice-sheet in the great Swiss valley, and find some other means of accounting for the travelled blocks on the Jura between Geneva and Soleure, or admit that the lower strata of a great glacier *can* travel up-hill and over hill and valley, and that the ice-sheets of the British Isles, of Scandinavia, and of North America merely exhibit the very same characteristics as those of Switzerland, but sometimes on a larger scale. We may not be yet able to explain fully how it thus moves, or what slope of the upper surface is required in order that the bottom of the ice may move up a given ascent, but the fact of such motion cannot any longer be denied.

Prof. T. E. Thorpe contributes a chatty paper on "Carl Wilhelm Scheele," whose life's work is summed up as follows :—

We owe to Scheele our first knowledge of chlorine and of the individuality of manganese and baryta. He was an independent discoverer of oxygen, ammonia, and hydrochloric acid gas. He discovered also hydrofluoric, nitrosulphonic, molybdic, tungstic, and arsenic acids among the inorganic acids ; and lactic, gallic, pyrogallic, oxalic, citric, tartaric, malic, mucic, and uric among the organic acids. He isolated glycerin and milk-sugar ; determined the nature of microcosmic salt, borax, and Prussian blue, and prepared hydrocyanic acid. He demonstrated that plumbago is nothing but carbon associated with more or less iron, and that the black powder left on solution of cast iron in mineral acids is essentially the same substance. He ascertained the chemical nature of sulphuretted hydrogen, discovered arsenetted hydrogen and the green arsenical pigment which is associated with his name. He invented new processes for preparing ether, powder of algaroth, phosphorus, calomel, and *magnesia alba*. His services to quantitative chemistry included the discovery of ferrous ammonium sulphate, and of the methods still in use for the analytical separation of iron and manganese and for the decomposition of mineral silicates by fusion with alkaline carbonates.

To this long list of successful labours must be added the memoir on "Air and Fire," which appeared in 1777, and the experimental material for which was partly collected in Malmö and Stockholm before 1770, and partly during Scheele's stay at Upsala, that is, prior to 1776. These dates, Prof. Thorpe reminds us, are important in view of Scheele's relations as a discoverer to Priestley and Lavoisier.

"The Geographical Evolution of the North Sea" forms the subject of an article by Mr. A. J. Jukes-Browne in the *Contemporary*. In the course of the paper the following conclusion is arrived at :—

The North Sea—that is to say, a sea lying east of Britain and opening northward—had no existence until after the formation of our Coralline Crag. The great change which submerged the northern land-barrier and permanently lowered the temperature of eastern England by letting in the waters of the Arctic Ocean took place during the formation of the newer "Crags" which overlie the Coralline Crag in Suffolk, and extend northward through Norfolk.

In proof of this statement, two salient facts may be mentioned : (1) the incoming and gradual increase in the number of northern species among the mollusca of the newer Crags ; (2) the occurrence of Crag shells in the glacial sands of Aberdeen, showing that marine Pliocene deposits once existed at no great distance from the Scottish coast and were destroyed by the ice of the Glacial Period.

According to Mr. Jukes-Browne, towards the close of the Pliocene period the whole area between East Anglia and the Netherlands appears to have become dry land. The estuary of the Rhine then lay off the coast of Norfolk, and the Thames was one of its tributaries. During the glacial epoch, the whole bed of the North Sea was dry land. The subsidence that afterwards submerged the North Sea floor and filled the valley of the English Channel with water, led to the silting up of the English river-valleys, and to the formation of the modern delta of the Rhine. Mr. Jukes-Browne believes that by it England was separated from the Continent ; for there is no proof that a continuous sea separated England and France at any earlier Pleistocene epoch.

The *Forum* (October) contains a contribution by Prof. E. S. Holden, the object of which is "to detail the history of the remarkable 'new star' of 1892, in the constellation Auriga." On this side of the Atlantic, a detailed account is understood to mean a more or less minute narration of particulars ; but Prof. Holden's paper shows us that in writing the history of a new star in detail, reference to some of the most important communications on the matter may be omitted. "The *Nova* was, no doubt, a star like our sun . . . ," says Prof. Holden. ". . . Let us imagine what fate ours would be, if our sun should suddenly increase in light and heat some hundreds of times, and then fall off some thousands," and so on. The learned Director of the Lick Observatory will find that there is very little, if any, evidence that Nova Aurigæ "resembles our sun" in physical constitution, which is the inference naturally put upon his remarks. We read that, "Nothing can be clearer than the identity of the 1893 spectrum of the *Nova* and that of the nebulæ"—a pill which some spectroscopists have had great difficulty in swallowing. Prof. Holden describes Prof. Seeliger's hypothesis of the genesis of the Nova, but inclines to Prof. Vogel's modification of it ; for he remarks, "We can at least say that up to the present time the new star has behaved as if it had entered a system of distant planets, rather than a swarm of cosmical meteorites." This, however, is simply an expression of opinion, and the statements that might justify it are not discussed, for the reason that "they relate to the minutiæ of observation."

The *Quarterly Review* (October) contains an excellent account of Vedic mythology, which should be of interest to astronomers, since it deals chiefly with the relation of the sun and moon to mythological thought and language.

An article on "Waves," in *Good Words*, and one on "Electricity and Health," in the *Humanitarian*, deserve mention, though neither contain much of scientific importance.

The *Medical Magazine* contains Part I. of an article on "Heredity and Disease."

ON A METEORITE WHICH FELL NEAR JAFFERABAD IN INDIA ON APRIL 28, 1893.[1]

PARTICULARS have recently reached this country concerning the fall of a meteorite near Jafferabad in the south-east of Kathiawar, a native State adjoining the

[1] Note read at the meeting of the Mineralogical Society, October 14, 1893.

Bombay presidency. Dr. J. W. Evans, the geologist to the State of Kathiawar, has kindly forwarded to me a translation of the report sent in by the local official. It is curious that a fall of Nagali Jaowar (a kind of seed used as food by the poorer people of the country) is said to have occurred at the same time as the fall of the stone. As suggested by Dr. Evans, the seed may have been carried a short distance by the wind, which is very strong on the coast of Kathiawar at the time of year when the fall occurred. The spot where the fall took place is a flat region of recent limestone. Dr. Evans adds that the official report is interesting, as it is the account of a man who never heard of a meteorite, and to whom the fall of grain is as probable as that of stones. The report is as follows :—

"There was thunder which lasted for a quarter of an hour on the southern side at between a quarter to eight and eight o'clock in the morning of April 28, 1893. At that time the sky was clear enough. It has been known that the thunder was heard in nearly all the villages of Babariawad. The reason for my giving you this trouble is that Nagali Jaowar has rained with thunder on a small piece of ground near the outskirts of a village called 'Wad,' situate on the eastern bank of a river named 'Dhatarwadi,' and about two kosh (miles) distant from this place, but there was not a drop of rain-water. A specimen of Jaowar that has come down is sent herewith. A coolie, named Hamo Shiyal, while working in his field on the same day and at the same time, saw a stone about five or seven tolas (a tola = 180 grains) in weight falling on to the ground, about two fields distant, on the southern side of a village called Covaya, situated south-west of, and three kosh distant from this place, with the noise of thunder. He picked it up, and came to the village with it. While showing it to the people of the village, they broke it to pieces. As a specimen, one piece of the stone, out of the two pieces found by inquiry, is also sent herewith. There was not a drop of rain, and the sky was clear enough. Notwithstanding the clearness of the sky, it has been said that there was a thunderbolt. Such were the details of the occurrence on the morning of Friday, at between a quarter to eight and eight. If any further details come to notice, they will be reported to you.'

The original stone was shown by Dr. Evans' investigations to have been 3·7 centimetres long, 2·9 centimetres broad, and 2·3 centimetres thick. It was broken up by the villagers, and only the two largest portions have been recovered by the officials. These weigh respectively 17·4 and 16·3 grammes. The stone is said to have been cold when picked up, and no hole in the ground made by its fall was noticed. The larger fragment of this meteorite has been entrusted to me by my friend Dr. Evans, and Mr. L. Fletcher, F.R.S., of the British Museum, has kindly made a preliminary examination of it, the results of which I give in his own words :—

"The fragment of stone weighing 17·42 grams (3/5ths of an ounce), sent by Dr. Evans, is undoubtedly part of a true meteorite, as is seen at once on examination of the crust and the fractured surface. The crust formed during the passage of the stone through the earth's atmosphere is dull black in colour, and in parts so rough as to be scoria-like in texture. On direct comparison with the stones from other falls preserved in the British Museum it is seen that in these respects the Jafferabad stone is very similar to parts of Pavlograd, Bachmut, Middlesborough, Tourinnes-la-Grosse, Pohlitz, and Gross-Liebenthal. The crust, however, is very remarkable for its thickness, which a little exceeds a millimetre, and at one part even reaches two millimetres: in most meteoric stones the thickness of the crust does not exceed half a millimetre, and in very few cases reaches a millimetre: the thickness in this instance surpasses that of the crust of any specimen preserved in this collection: of the above-mentioned meteorites, Pavlograd approaches most nearly in this respect. The broken surface of the stone is very white in colour, and shows the usual metallic spangles of nickel-iron and troilite, white and tomback brown respectively; the thin black veins, beginning at the crust and traversing the stone in various directions of former fracture, are unusually conspicuous, even more than in the case of the stone which fell at Gross Liebenthal in Russia on November 19, 1881, and which is very similar in its general characters. The aspect of the fracture is very uniform, and no round enclosures (chondrules) are to be distinguished. This, however, is often the case, even when chondrules are actually present, and in all probability a microscopic section of the Jafferabad stone, when allowed by the owner to be made, will reveal their presence. The specific gravity of the stone with crust is 3·55, and has an average value; that of Pavlograd, for instance, is 3·58."

It will be seen from the foregoing account that the Jafferabad meteorite presents some features of considerable interest; and it is to be hoped that, in the interest of science, his Highness the Nawab of Junagadh may permit the specimen now in this country to be subjected to a full microscopical and chemical examination.

JOHN W. JUDD.

NOTES.

THE following is a list of names recommended by the President and Council of the Royal Society for election into the Council for the year 1894, at the anniversary meeting on November 30 (the names of new officers are printed in italics) :—President: Lord Kelvin. Treasurer: Sir John Evans, K.C.B. Secretaries: Prof. Michael Foster and Lord Rayleigh, Foreign Secretary: *Sir Joseph Lister, Bart.* Other Members of the Council: Prof. Isaac Bayley Balfour, *Dr. Andrew Ainslie Common, Dr. Andrew Russell Forsyth,* Richard Tetley Glazebrook, *Prof. Alexander Henry Green, Sir John Kirk, K.C.B., Prof. Oliver Joseph Lodge, Sir John Lubbock, Bart.,* William Davidson Niven, Dr. William Henry Perkin, The Marquis of Salisbury, K.G., *Prof. J. S. Burdon Sanderson,* Adam Sedgwick, *Prof. Thomas Edward Thorpe,* Prof. William Augustus Tilden, *Prof. W. Cawthorne Unwin.*

IT is with deep regret that we announce the death of Sir Andrew Clark, Bart., on November 6, at the age of sixty-seven.

BY the death of Prof. E. Lecouteux, France has lost one of its foremost agriculturists. Lecouteux was born at Créteil (Seine) in 1819. He was one of the founders, and afterwards a vice-president, of the Société des Agriculteurs de France. He was also at one time president of the Société Nationale d'Agriculture. Many important additions to agricultural literature were made by Lecouteux, and the effects of his beneficial influence will be apparent in France for many years to come.

THE Municipal Council of Paris has had an elegant album designed for M. Pasteur, containing the address presented to him in the name of the city of Paris at the celebration of his seventieth birthday in December of last year.

BRUSSELS UNIVERSITY will shortly have a laboratory of Psychological Physics, endowed by private munificence. The Rector, Prof. M. H. Denis, has nominated Drs. G. Dwelshauvers and P. Stroobant to take charge of the researches and practical work.

DR. JOHN ANDERSON, F.R.S., who for the past two years has been collecting materials in Egypt for a work on the mammals and reptiles of that country, is, we understand, again returning to Egypt to continue his researches, proceeding in the first instance to Suakin.

Prof. Guido Cora, of Turin, in 1886 a gold medallist of the R.G.S., has received this year a special gold medal from the Imperial Russian Geographical Society of St. Petersburg.

Mr. Charles Stewart has been elected Fullerian Professor of Physiology to the Royal Institution of Great Britain, the appointment to date from January 13, 1894.

Dr. von Jhering has been appointed Director of the Natural History Museum, Sao Paulo, Brazil.

Dr. Woldrich, Vienna, has been nominated Professor of Geology in the Bohemian University of Prague.

Dr. T. Pleske has been elected to the Directorship of the Zoological Museum of the St. Petersburg Academy of Sciences, in the place of the late Prof. A. Strauch.

Dr. Carl Berg has been reappointed Professor of Zoology at the University of Buenos Ayres, a chair he occupied between 1875 and 1890, and which remained vacant after he went to Monte Video.

Prof. G. E. Hale is expected to be present at the meeting of the Royal Astronomical Society to-morrow, and to give an address on the subject of his solar researches.

In Nature of July 20 (vol. xlviii. p. 268) we published a communication from Prof. P. F. Frankland, calling attention to certain objections which had been raised by some members of the Society for Promoting Christian Knowledge against the publication of his little book, "Our Secret Friends and Foes," in the Romance of Science Series. The objections were stated formally by the Secretary of the Victoria-street Anti-Vivisection Society, and endorsed in most forcible terms by Lord Coleridge, as set forth in the correspondence published in our issue referred to. The protest calling upon the S.P.C.K. to withdraw the book from circulation, on the ground that it favoured "experiments upon living animals," was handed in last July with some fifty signatures attached, and in accordance with a rule of the Society was submitted to the Standing Committee, whose judgment in matters of this kind is considered final. This Committee has just passed the following resolution :—"The Standing Committee having taken into consideration the statement of objections, made under Rule xxxvi., against the book entitled "Our Secret Friends and Foes," by Prof. P. F. Frankland, and the remarks thereon submitted respectively by the author and the General Literature Committee, are unable to see sufficient reason for withdrawing the book from the Society's list." The decision arrived at will give general satisfaction to English men of science, and forms a fitting sequel to the correspondence forwarded to us by the author of the book.

At last there is a possibility that a scientific method of identification will become part of our prison system. The Home Secretary has appointed a committee to consider the means at present available in this country for the identification of habitual criminals, and to report to him whether they could be improved by the adoption either of the Bertillon method of identification in use in France, or of Mr. Galton's finger-print method, or in any other way. The report will be awaited with interest.

The Exhibition of the Photographic Society of Great Britain will close on Wednesday, November 15.

An International Congress of Applied Chemistry will be held at Brussels on August 4, 1894.

The Russian Chemical Society will celebrate its twenty-fifth year of existence by a special meeting at St. Petersburg on November 18.

The Newcastle-on-Tyne and Northern Counties Photographic Association propose to hold an international photographic exhibition next April.

An "Exposition Universelle" will be opened at Lyon on April 26, 1894, and will remain open until the following November. Sections will be devoted to electricity, hygiene, and agriculture.

At the meeting of the Museums' Association, held in July last, under the presidency of Sir W. H. Flower, K.C.B., F.R.S., the following officers were elected by the Council :—Dr. V. Ball, C.B., F.R.S., to be president, Prof. D. J. Cunningham, F.R.S., and Mr. Walter Armstrong vice-presidents. The Association will meet in Dublin next year, about the end of June or the beginning of July.

The new session of the Royal Geographical Society will commence on November 13, when the president, Mr. Clements R. Markham, C.B., F.R.S., will discourse on "Geographical Desiderata, or Exploring Work to be done and Geographical Problems to be solved." On November 27, Dr. John Murray will read a paper on "The Antarctic Region and the Scientific and Commercial Results of its Exploration."

The seventy-fifth session of the Institution of Civil Engineers will be commenced on November 14, and the meetings before Christmas are likely to be occupied, in addition to an address from Mr. Giles, president, with the design and construction of impounding reservoirs for water-works at Tansa (Bombay), Baroda, and Jeypore, with machinery for the manufacture of casks, and with the development of hydraulic power-supply in London.

The first meeting of the 140th session of the Society of Arts will be held on Wednesday, November 15, when the opening address will be delivered by Sir Richard E. Webster, M.P. A course of Cantor lectures will be given by Prof. Frank Clowes in January and February next, his subject being "The Detection and Measurement of Inflammable Gas and Vapour in the Air." Captain Abney will deliver three Cantor lectures on "Photometry" in April. The following are among the papers down for reading after Christmas :—"London Coal Gas and its Enrichment," by Prof. Vivian Lewes ; "Experiments in Aeronautics," by Mr. Hiram S. Maxim ; "Pewter," by Mr. J. Starkie Gardner ; "Electric Signalling without Wires," by Mr. W. H. Preece, F.R.S. Two juvenile lectures on "Plants : their Foes and Defences," will be delivered by Mr. W. Gardiner, F.R.S., in January.

It is reported that Vesuvius is in a state of activity, and streams of lava are distinctly visible at night.

An earthquake was distinctly felt in various parts of Wales and the West of England on Thursday, November 2, about 5.45 p.m. From reports of the occurrence we gather that at Milford Haven the tremor lasted about twelve seconds, and appeared to travel from north to south. In the St. Helens district of Swansea the shock lasted about five seconds. A distinct upheaval of the earth is reported from Carmarthen, where the shock is said to have lasted thirty seconds. Two successive shocks were felt at Cardigan, accompanied by a rumbling noise travelling from the sea in a south-easterly direction. In Pembroke there was a heavy rumbling sound, and the earth was felt to tremble for about seven seconds. The wave appeared to be travelling from south-east to north-west. Very faint shocks were felt at Cardiff and along the Rhondda Valley. In North Wales, however, the tremor was of a very pronounced character. Both shores of the Mersey seem to have been affected. From correspondents of the *Times* it appears that at Aigburth, just south of Liverpool, the vibration was felt at 5.44. At Woodside, on the Cheshire side of the Mersey, the time was

5h. 45m. 30s.: at Crosby, about five miles to the north of Liverpool, 5.47; at Shrewsbury 5.48, the duration in this case being estimated as three seconds. In Bristol it is reported that the tremor was distinctly felt along a course from north-west to south-east for forty seconds. Mr. H. Courtenay, writing to us from Waterford, says that the disturbance was experienced there at 5.25. Mr. Lloyd Bozward, of Worcester, describes the occurrence as follows:—"On Thursday last, at 5.45, a smart shock of earthquake was experienced. At this house the shock was vertical; no noise was heard, but in a second or two after the first shock a feeble one followed. Persons on the ground-floor observed nothing. The shock was felt at Boughton Park, southwards a mile hence, and there also the servants on the ground-floor felt nothing. These places are on the west side of the Severn. It is somewhat rare for the same shock to be felt on both sides of the Severn, but on this occasion it was somewhat severely felt at some large ironworks on the eastern side of the river. There the motion is described as a swaying one, and a rumbling like the passing of a heavy waggon was heard. At Boughton and the ironworks the time given is 5.48 p.m. I took the hour at the time of the shock from a clock, a good time-keeper, in the room with me. At Callow End, Dermstone, a farmstead ten miles north-east of Worcester, no shock was felt, but a loud noise was heard."

Dr. N. M. Glatfelter reprints from the fifth annual report of the Missouri Botanic Garden "A Study of the Venation of *Salix*." Photographic reproductions are given of the leaves of twenty-four American species of willow, and an attempt is made to classify them according to their venation.

The Deby collection of diatoms now in possession of the British Museum, and open for reference by students in the Cryptogamic Herbarium, is the finest in existence, both as regards the number of species, the authority of the nomenclature, and the beauty of their preparation and preservation. Besides those collected by M. Deby himself, it includes a large number of type-slides prepared by other eminent diatomists. The collection of diatoms in the British Museum is now estimated to amount to about 50,000 slides.

Dr. H. Wild, Director of the Central Physical Observatory at St. Petersburg, has published in German a summary of the decisions of the various international meteorological conferences, from that held at Leipzig in 1872 until that held in Munich in 1891. The arrangement is first under subjects, and secondly according to chronological order, and the work will be found very useful for reference by persons who may be seeking for information upon any particular subject, instead of having to consult some thirteen different volumes.

We have received the report on the operations of the German Meteorological Office for the year 1892, which closes an important period in the history of that institution, owing to the completion of the organisation of the rainfall stations which began with the year 1885, and the establishment of a first-class meteorological and magnetical observatory at Potsdam. The rainfall stations now number nearly 1900, and the stations which send special reports of thunderstorms exceed 1400. The report contains not only a list of the official publications for the year, but also a list of the contributions of the officials to both German and foreign periodicals. We also note that, in order to keep up an interest in the work, the office issues no less than 200 copies of the popular meteorological journal *Das Wetter* to its observers.

The report of the Director of the Royal Alfred Observatory, Mauritius, for the year 1891 has just reached this country. The maximum shade temperature during the year was 95°·4 on December 8, and the minimum 51°·0 on August 3. The highest temperature in the sun was 162°·7, and the lowest on the grass 46°·0. The rainfall amounted to 44·63 inches, being 3·15 inches below the average, but at some other stations in the island the rainfall was much greater than at the Observatory. Dr. Meldrum collects observations from ships visiting the island, for the preparation of meteorological charts of the Indian Ocean; the number of days' observations tabulated during the year amounted to 9,600, taken between 23° N. and 46° S. latitude.

Colonel A. T. Fraser has sent us an interesting note from Bellary with regard to two Hindoo dwarfs which he photographed in the Kurnool district of the Madras Presidency, not far south of the river Kistna. In speech and intelligence the dwarfs were indistinguishable from ordinary natives of India. From an interrogation of one of them, it appeared that he belonged to a family all the male members of which have been dwarfs for several generations. They marry ordinary native girls, and the female children grow up like those of other people. The males, however, though they develop at the normal rate until they reach the age of six, then cease to grow, and become dwarfs. These stunted specimens of humanity are almost helpless, and are quite unable to walk more than a few yards.

Mr. Miller Christy outlines a scheme for mapping the geographical distribution of vertebrate animals in the *Zoologist* for November. He proposes to construct a map showing, by means of different colours, the following points for each species:—(1) Its present (indigenous) area of permanent residence throughout the world; (2) its summer and winter ranges throughout the world (if migratory); (3) its relative abundance in different parts of its area; (4) its lines of migration (if any); (5) the additional area (if any) over which any species, now partly or wholly extinct, can be traced within historic times; (6) the additional area (if any) over which it has been naturalised by human agency; and (7) other points of interest, such as isolated occurrences, erratic movements, areas of hybridization, &c. Though it may be some years before a scheme of this kind is well under weigh, authors of monographs of genera or families would do well to systematise their works, so that they could easily be used in the compilation of a topographical catalogue or bibliography.

The extensive and increasing demand for india-rubber renders it possible that the supply will eventually become exhausted, so attempts at artificial cultivation of rubber trees are being made in various rubber-producing countries. Mr. Hart remarks, in the June *Bulletin* of the Royal Botanic Gardens, Trinidad, that rubber has been procured in the Gardens from *Castilloa elastica*, and that trees of a mature size will produce it in paying quantities. It has also been proved that *Heveas* of several species will thrive well in Trinidad. In this connection a paper by Dr. Ernst, on the caoutchouc of the Orinoco, published in the first number of the *Revista Nacional de Agriculture*, and included in the *Bulletin*, is of interest. Dr. Ernst says that the rubber of the Orinoco is extracted from the juice of the *Hevea braziliensis*, Müll, a tree belonging to the family *Euphorbiacea*, and not to that of the *Hevea Guayanensis*. The milky juice obtained from the trees, through incisions made in the bark, has the consistency of cream, and the rubber existing in it in minute globules constitutes from thirty to thirty-three per cent. of the weight. The rubber collectors of the Amazons employ the slow, primitive, and contaminating process of evaporating the juice in the dense smoke of a wood fire, in order to separate the rubber from it. A far better method of obtaining coagulation is to add a six per cent. solution of alum to the juice, and then submit the coagulated rubber to pressure in order to extract the water it contains. Dr. Ernst thinks that every effort should be made to extend and conserve the forests, thickets, or groves of rubber trees, suggesting, among other things, that

when the collectors work a grove they should be made to plant a certain number of trees. Only by such means, and by adopting a chemical mode of coagulation, can the rubber production of the Amazon territory be increased in quantity and improved in quality.

Mr. Vernon Bailey has prepared a report, for the U.S. Department of Agriculture, on the haunts and habits of the spermophiles, known in America as gophers or ground squirrels, inhabiting the Mississippi Valley region. Five distinct species of the genus *Spermophilus* inhabit this region, and four are restricted to it. On account of the immense damage done to crops by these mammals, several States have endeavoured to exterminate them, and they have formed the subject of investigation at a number of agricultural colleges and experimental stations. The increase of the pest is probably due to the thoughtless destruction of its natural enemies. We learn that no less than sixteen of the seventy-three species and sub-species of hawks and owls found in the United States are known to prey on the various members of the genus *Spermophilus*. Among mammals, the spermophile's enemies include the badger, fox, coyot, wild cat, and weasel, all of which are hunted and killed for sport or because of poultry-yard depredations. In several States immense amounts of money have been paid as bounties for the destruction of the pest, but the results are far from satisfactory; and it is evident that a bounty is only a temporary expedient for the extermination of these or any other animals. Mr. Bailey says that in many ways spermophiles render valuable service to the farmer, so he does not recommend a complete destruction of them. The evil which they do to crops, however, is very considerable over more than two-thirds of the United States; hence there is a general demand for some economical means of destroying them. The animals can, of course, be shot, and in this way limited areas may be freed from their ravages. Fumigation and trapping have also been employed with more or less success; but the most effective and quickest results have been obtained by placing in the burrows a bunch of rags or waste saturated with carbon bisulphide, and closing up the hole. The information on this point given by Mr. Bailey should be of use to agriculturists; indeed, the whole of the bulletin is of high importance.

At the request of the Royal Academy of Science in Vienna, Prof. V. Hirbel undertook a geological tour this season in Thessaly. One or two short reports from him are published in the journal of the *Mathematics naturwissensch. Classe* (No. 20, October 12). Respecting the geology of Northern Greece, he writes that calcareous formations of the Flysch have the most extensive outcrop on the three parallel chains of the Pindus range. Dykes of serpentine intrude through the Flysch, and occur as flows interbedded with the overlying Cretaceous limestones. The age of the much larger intrusive masses of serpentine in the sandstone zone of the upper Peneus has not yet been definitely ascertained.

In the "Proceedings of the U.S. National Museum" (vol. xvi. pp. 471-478, pl. 56), Mr. William Healey Dall describes a "Sub-tropical Miocene Fauna in Arctic Siberia." This fauna consists of a few well-preserved specimens of molluscan genera, Ostrea, Siphonaria, Cerithium, &c., which were found in 1855 by a member of the "Ringgold and Rodgers Exploring Expedition in the North Pacific." The fossils occur in Miocene sandstones of the Sea of Okhotsk, which are exactly like those of the Alaskan coast, and they are of interest chiefly because they prove beyond doubt strong affinities of the Miocene mollusca of these northern seas with species now living in the warm seas of Japan and China. According to Mr. Dall, the annual mean temperature of the waters in the Okhotsk area has diminished by at least 30° to 40° F. since Miocene time.

The U.S. National Museum has also published a report by Mr. James I. Peck, on the pteropods and heteropods collected by the U.S. Fish Commission steamer, *Albatross*, during the voyage from Norfolk, Va., to San Francisco in 1877-8. The pteropod collections of this voyage are, for the most part, from the Caribean and Panamaic provinces, and the material belongs almost exclusively to the family Cavoliniidæ. From none of the deeper dredgings in the Pacific were pteropod deposit shells reported, though at times the surface collections in the same regions showed an abundance of the live animals. Mr. Peck agrees with Agassiz that bottom distribution is largely determined by the course of the ocean currents, so that by means of pelagic fauna and their bottom distribution, light may be thrown upon the course of the currents. To this cause Agassiz ascribed the presence of Arctic pteropods along the New England coast, from the course of the Labrador currents, and Mr. Peck believes that the differences between the bottom and surface collections of the *Albatross* on the voyage in the Gulf of Panama and at the Galapagos Islands may be similarly explained.

Some years ago, a discovery of fossil plants was made for the first time in the Trinity Division of the Comanche series of Texas. These have now been worked out in detail by Mr. Wm. Morris Fontaine, who has published his results, together with a series of illustrative plates, in the "Proceedings of the U.S. National Museum" (vol. xvi. pp. 261–282, pl. 36-43). There are twenty-three species described; by far the greater number are conifers belonging to the genera Abietites, Laricopsis, Pinus, Frenelopsis, Sequoia, &c., a few Cycad genera, and a new species of Equisetum are also present; ferns are of exceedingly rare occurrence, and angiosperms entirely wanting. Seven of the species have been identified with forms from the Lower Potomac deposits (Lower Cretaceous) of Virginia, and several others show striking points of similarity with the same flora; four species agree with Wealden types. The whole character of the "Trinity" flora, more especially the absence, so far as known, of angiosperms, seems in favour of Jurassic as well as Cretaceous affinities. It certainly does not bear the distinct Cretaceous impress of the flora in the Potomac or Wealden formations. Mr. Fontaine refers the "Trinity" flora, therefore, to the base of the Cretaceous deposits in Texas, occupying a slightly lower horizon than the very similar flora in the Potomac deposits of Virginia.

The recent geological history of the Arctic lands is discussed by Sir Henry Howorth in the *Geological Magazine*. The general conclusions to which he arrives are as follows:—(1) During the Pleistocene period the Arctic lands, instead of being overwhelmed by a glacial climate, were under comparatively mild conditions, and were the home of a widely-spread and homogeneous fauna and flora, constituting, perhaps, the best defined life-province in the world. (2) Since Pleistocene times the climate of these Arctic lands has been growing more and more severe, resulting in the extinction of a portion of their vegetable and animal inhabitants. (3) While one portion of this Pan-Arctic fauna and flora still remains largely homogeneous, another portion has become differentiated by evolution in Northern America and Northern Europasia, into the Nearctic and Palæarctic regions respectively. (4) The true and the only glacial climate which we know to have prevailed in the Arctic lands was not during the so-called glacial age of geologists, that is during the Pleistocene period, but in that which is now current, and which is the product largely, if not entirely, of changes of level in the earth's crust which have occurred since Pleistocene times.

The "Geology of Dublin and its Neighbourhood" has found a clear interpretation at the hand of Prof. Sollas, of Dublin University (*vide* Proceedings of the Geologists' Association, August,

pp. 91–121). Prof. Sollas discusses the origin of the ancient quartzites, grauwackes, and slates in that district, and gives drawings from microscopic sections to illustrate the evidence in favour of their originally sedimentary nature. Palæontological evidence is present in the form of numerous worm-tubes and the doubtful organic remains known as Oldhamia radiata and antiqua. The whole group is regarded as a deposit in the tranquil sea of a period, probably Cambrian or pre-Cambrian, which he rather happily characterises as the "Age of Worms." Just as in the Highlands of Scotland, this Irish area has been subjected to great earth-movements, not only once, but several times. First, in later Cambrian age, the sedimentary rocks were rolled up into a series of anticlinal and synclinal folds. Ordovician time saw the rocks once more below sea level, and a second elevatory movement set in with extreme slowness in Upper Ordovician time. The third period of movement is of post-Carboniferous date, and of simpler character than the two preceding, the flexures having in the main followed those of the Ordovician movements. In his concluding pages Prof. Sollas briefly refers to the absence of mesozoic and tertiary deposits, the general characters of the glacial period, and the distribution of the boulder-clay over the Dublin area. Sketch maps and diagrams illustrate the paper.

THE effect upon the optical properties of a plate of quartz of compressing it in a direction perpendicular to its axis has been investigated by M. F. Beaulard, who publishes his results in the *Journal de Physique*. A quartz plate was cut normally to the axis and compressed laterally, thus superimposing a double refraction, varying with the pressure, upon the rotatory power. Allowing a beam of plane-polarised light to fall normally on to the plate, he obtained inside the crystal two elliptic vibrations propagated with different velocities and exhibiting after emergence a certain difference of phase. These two vibrations interfered and gave an ellipse whose elements could be experimentally determined. The pressures were obtained by means of a Perreaux dynamometer, varying from 0 to 530 kgr. per square cm. The quartz was placed between two jaws which could be made to approach each other by turning a screw. One of the jaws was fixed firmly in a frame, the other moved on guides which communicated the pressure to an elliptical pair of springs, the amount being indicated on a dial through a rack and pinion arrangement. The dynamometer was mounted on two wooden platforms allowing of the orientation of the quartz plate normally to the incident ray. The rest of the apparatus consisted of a polariser, a quarter-wave mica plate, a pair of quartzes with two different rotations, an analyser, and a spectroscope with eye-piece slit. It was found that the rotatory power remains constant; that the difference of phase due to double refraction alone is proportional to the pressure, and that the angle between the major axis of the emergent ellipse and the original incident vibration increases at first with the pressure (for plates of given thickness), then oscillates, and at particular pressures the two directions are the same, so that at some points the major axis turns in a direction contrary to the natural rotation of the quartz plate.

AT a recent meeting of the Académie des Sciences (Paris), M. Poincaré communicated an account of the experiments on the velocity of propagation of an electric disturbance along a wire, which have been carried on by M. Blondlot at Nancy. The wires used were of "high conductivity" copper, 3 mm. in diameter, and were fixed to the telegraph posts between the Préfecture and the Maxeville Asylum, a distance of about one kilometre. The method employed was very like that used by Wheatstone in his attempt to measure the velocity of the passage of an electric discharge, only instead of a rotating mirror M. Blondlot uses a rotating photographic plate. Matters are so arranged that two sparks pass between two knobs, one direct and the other after travelling round the 2 kilometre circuit. The mean of five experiments gives a velocity of 296 kilometres per second, the retardation being $\frac{1}{150}$ of a second. On a line 2 kilometres long, that is, one where the electricity has to travel over 4 kilometres, the velocity obtained was slightly greater, namely 298 kilometres per second.

IN a paper read before the American Institute of Electrical Engineers, Messrs. Bedell, Miller, and Wagner give an account of a new form of contact-maker which they have employed in their experiments on transformers. The contact-maker was required to connect for an instant a voltameter with the circuit of the transformer at any required part of the cycle. The instrument consists of discs carried by a spindle which was connected to the shaft of the dynamo. A needle projects from the face of this disc and forms one of the electrodes for making contact, the other being formed by a fine water-jet issuing from a nozzle which is insulated from the rest of the instrument. The water-jet is supplied by a jar of water, several feet above, the connection being through a rubber tube. The nozzle of the water-jet is carried by a disc which is capable of being rotated, and has its edge graduated in degrees. The needle cuts the water-jet near the nozzle before the continuous column has had time to break up into drops. It was found necessary to put a little salt in the water, as pure water does not work, while acidulated water corroded the nozzle. This form of contact-maker the authors find far superior to any of the usual mechanical devices, the contact being perfectly constant and reliable.

IN the *Zeitschrift für physikalische Chemie*, vol. xii. No. 4, Herr Humburg gives an account of a significant piece of work which was undertaken for the purpose of obtaining additional evidence as to whether the magnetic rotatory polarisation of solutions gave any support to the hypothesis of electrolytic dissociation. Measurements were made on solutions of the lower fatty acids in water, benzene, and toluene. The molecular rotation of the dissolved substance was calculated on the supposition that the value found for the solution was the sum of those given by the amounts of solvent and dissolved substance which it contained. The numbers thus obtained were found to be practically independent of the concentration and of the chemical nature of the solvent, and were identical with the values given by the free acids. Not only was this the case with acids such as acetic, proponic, and butyric, which are held to be but feebly dissociated in aqueous solution, but also of the chlor-acetic acids, which are supposed to be much more strongly dissociated. Similar results were obtained from observations on solutions of various inorganic salts, such as potassium iodide, sodium bromide, ammonium nitrate, and barium bromide in water, and in methyl alcohol. Although the molecular conductivity of the aqueous solution of any of the salts was invariably much greater than that of the alcoholic solution, nevertheless the molecular rotation of the salt was the same in both cases. In conjunction with the work of Schönrock on this subject (see Notes, vol. xlviii. p. 230), the above results indicate that the effect of electrolytic dissociation on the magnetic rotatory polarisation of solutions (if such an effect really exists) is too small to be detected by ordinary methods of measurement.

ALTHOUGH such a large number of investigations have been made on the bacterial contents of waters derived from such different sources as lakes, rivers, springs, and wells, only a few observations have been made on the microbial condition of sea-water. Giaxa's are the earliest recorded examinations, and exhibit the poverty in this respect of sea-water. Thus, in the Bay of Naples, at about a mile and a half from the shore, only ten organisms were found in 1 c.c. Russell, also working in this bay at distances of 2½ to 9 miles from the coast, obtained

from 64 to 6 n 1 c.c. respectively. Very different is, however, the bacterial condition of sea-mud, as many as 245,000 microbes being found in 1 c.c. of slime at a depth of 164 feet, and 12,500 at 1,640 feet, whilst sea-water examined at such depths contained 121 and 22 respectively. Russell has been recently extending his observations (*Botanical Gazette*, vol. xvii. 1892) to the sea-water and mud on the Massachusetts coast. The number of bacteria, both in the water and slime, was very much less in these more northern and cooler waters than in the Mediterranean at Naples. The microbes present in the mud from Buzzard's Bay average from 10,000 to 30,000 per c c., being but a very small fraction of the number found in Mediterranean mud at equal depths. Samples of mud were also obtained about 100 miles from the shore at a depth of 100 fathoms, on the edge of the great continental platform skirted by the Gulf Stream. These samples are the farthest from land that have ever been bacteriologically examined, and bacteria were found in large numbers; moreover, the two prevailing varieties present were identical with those obtained near the Massachusetts coast. As in his earlier researches, Russell also here found but few varieties of bacteria in the mud, mostly two or three, and curiously one form, *Cladothrix intricata*, isolated from Mediterranean mud and frequently met with, was only rarely found in this Atlantic slime.

ETHYL and methyl derivatives of hydroxylamine, in which the alkyl radicles replace an atom of the hydrogen in the amido group, and are therefore directly linked to nitrogen, have been isolated by Dr. Kjellin, of Heidelberg, and their mode of preparation and properties are described in the current number of the *Berichte*. They have been obtained by the decomposition with hydrochloric acid of the esters of meta-nitro-benzaldoxim, which oxim was merely selected on account of its ready preparation in a state of purity. The process consisted in boiling the ester with seven times its volume of concentrated hydrochloric acid in a flask to which a reflux condenser was attached, subsequently cooling, saturating the liquid with hydrochloric acid gas, and again boiling for a few minutes. A large quantity of meta-nitro-benzaldehyde is deposited and removed by filtration, after which the hydrochloride of the substituted hydroxylamine is obtained by evaporation, first over a water bath, and finally over sulphuric acid. In order to isolate the free bases from the hydrochlorides, the same method was adopted as proved so efficacious in the isolation of hydroxylamine itself, namely, decomposition with sodium alcoholate, and subsequent fractional distillation of the resulting liquid *in vacuo*. The hydrochloride was dissolved in the minimum quantity of methyl alcohol, and a little less than the calculated quantity of sodium methylate added, the large evolution of heat being controlled by extraneous cooling. The deposited sodium chloride was removed by filtration through asbestos: filter paper cannot be employed on account of the strongly corrosive properties of these methyl and ethyl derivatives of hydroxylamine. Upon distillation *in vacuo* in the case of the methyl compound, after the greater portion of the methyl alcohol has passed over and at a temperature of 35–40°, an alcoholic solution of the base distils, then finally the free base admixed with a small proportion of alcohol. Upon submitting this last fraction to redistillation, at a temperature of 62° and a pressure of 15 m.m., the pure β-methyl hydroxylamine, $CH_3NH.OH$, distils as a colourless liquid, which solidifies to a solid composed of colourless and odourless prisms upon cooling with ice or agitation of the receiver. The crystals melt sharply at 42°, but do not resolidify until the much lower temperature of 20° is reached. Upon distillation *in vacuo* in the case of the ethyl compound, after the methyl alcohol has largely passed over an alcoholic solution of the base distils for a short time, then lastly the ethyl compound itself commences to sublime and condenses in the receiver in the form of large leafy crystals, filling the whole receiver. After pressing the crystals on porous plates to remove any superficial oil, pure β-ethyl hydroxylamine $C_2H_5NH.OH$ is obtained; the crystals are quite colourless and odourless, and exhibit a mother-of-pearl lustre. They melt sharply at 59–60° without decomposition.

THE β-methyl and β-ethyl derivatives of hydroxylamine are substances which are readily soluble in water and lower alcohols, but only very slightly in ether and benzene. The crystals of both deliquesce in moist air. In the case of the methyl compound the deliquesced substance rapidly volatilises; but in the case of the ethyl compound the deliquescence can only be observed in badly-stoppered bottles, for in the open air the spontaneous volatilisation is so rapid that the substance has not time to deliquesce before it entirely disappears. Both compounds react strongly basic, and reduce alkaline copper and silver solutions as energetically as hydroxylamine itself in the cold. They strongly attack organic substances, but do not etch glass, nor do they appear to be explosive substances like free hydroxylamine. Both compounds are rapidly destroyed by halogens with production of halogen acids; concentrated hydriodic acid converts them to amines. When heated for some time in a sealed tube with concentrated hydrochloric acid, the methyl compound suffers an interesting change, being converted into ammonia and formaldehyde—$CH_3NH.OH = NH_3 + HCOH$.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include another living specimen of *Lima Loscombii*, the Holothurian *Thyone fusus*, and the rare Nemertines *Carinella polymorpha* (second specimen), *Cerebratulus marginatus* (first record), and a large *Lineus bilineatus* (16 cm. long). The tow-nettings have been of a uniform character. The diatom *Coscinodiscus* has been present in remarkable profusion for several weeks past. Medusæ have been scarce. The most plentiful larvæ are those of Polychaetes, of Cirrhipedes, the *Mysis* stages of several Decapods, and *Scyphonautes*. Veligers are present in small numbers; and isolated specimens of the larvæ of *Cephalothrix*, *Porcellana* and *Carcinus* (*Megalops*) have also been observed. Very few individuals of *Crangon vulgaris* are now to be found bearing ova.

THE additions to the Zoological Society's Gardens during the past week include a Black-handed Spider Monkey (*Ateles geoffroyi*) from Nicaragua, presented by Mr. T. E. M. Rymer-Jones; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Miss G. A. Gollock; two Macaque Monkeys (*Macacus cynomolgus*, ♂ ♂) from India, presented respectively by Mr. W. Wylde and the Hon. Mrs. E. Yorke; a Philippine Deer (*Cervus philippinus*, ♀) from Manila, presented by Capt. T. E. Saunders; seven Common Quails (*Coturnix communis*), two Common Terns (*Sterna hirundo*), two Common Toads (*Bufo vulgaris*) European, two Bull Frogs (*Rana catesbiana*) from North America, a Grey-headed Porphyrio (*Porphyrio poliocephala*) from India, presented by Mrs. Rickards; a Smooth Snake (*Coronella lævis*) British, presented by Mr. A. Green; a Bay Wood Owl (*Phodilus badius*) from Java, deposited; two Rose-Hill Parrakeets (*Platycercus eximius*) from Tasmania, a Purple Sandpiper (*Tringa striata*) British, purchased.

OUR ASTRONOMICAL COLUMN.

A NEW SOUTHERN STAR.—Prof. Krueger has received a telegram from Prof. E. C. Pickering to the effect that a new star was discovered by Mrs. Fleming on October 26. Its Right Ascension is given as 230° 34′, and its North Polar Distance = 140° 14′. The magnitude on July 10 = 7·0. No further details have been received, but from the date for which the magnitude is given it is probable that the star was detected by

Mrs. Fleming upon a photographic plate taken in July. The telegram has been communicated to the observatories in the southern hemisphere.

"ASTRONOMICAL JOURNAL" PRIZE.—Owing to the fact that during the past six months only one comet has been discovered, and that its period of visibility was unusually short, and also to the probable prevalence of a bad time of observing weather during the winter, the period specified in the offer of this prize for observation of comets has been extended by six months. The closing time for this prize will now take place September 30, 1894.

COMET BROOKS (OCTOBER 16).—Last week we gave Bidschof's elements and ephemeris for this comet. This week, for the sake of comparison (*Astronomischen Nachrichten*, No. 3194), we give the elements of the comet as obtained from the observations made at Hamburg, October 17; Greenwich, October 18; Pola, October 19; Strassburg, October 23, and Vienna, October 24. They are as follows:—

Elements.

T = 1893 September 19·209 M.T. Berlin.

$$\left.\begin{aligned} \omega &= 347^\circ\ 20'\cdot 50 \\ \Omega &= 174\ 53\cdot 20 \\ i &= 129\ 45\cdot 77 \end{aligned}\right\} 1893\cdot 0$$

$\log q = 9\cdot 90992$

The current ephemeris is for 12h. Berlin mean time.

1893.	α App. h. m. s.	δ App. ° ′	Br.
Nov. 9	12 58 50	+30 27·2	0·82
10	13 0 53	31 20·6

Unit of brightness occurred on October 17.

MOON PICTURES.—In an article on the "Origin of the Lunar Craters," which has appeared in the last two numbers of *Prometheus* (Nos. 212, 213), the writer has been able to secure some excellent illustrations. These pictures are copies from photographs taken at Paris by the Brothers Paul and Prosper Henry, and illustrate regions near the South Pole. The current number of *Knowledge* also contains two fine reproductions of lunar photographs obtained by MM. Henry, illustrating an article by Mr. A. C. Ranyard, on the tints of the lunar plains.

METEOR SHOWERS DURING NOVEMBER.—During this month, in addition to some minor showers, Mr. Denning's table informs us that there are two which are above the usual brilliancy. The positions of the radiant points are as follows, the two most brilliant being printed in heavier type:—

Date.	Radiant. α	δ	Meteors.
Nov. 13	**150**	**+22**	Swift; streaks
16	154	+ 41	Swift; streaks
17	53	+ 71	Slowish
20	62	+ 23	Slow; bright
27	**25**	**+44**	Very slow; trains
30	190	+ 58	Swift; streaks

GEOGRAPHICAL NOTES.

SOME anxiety may have been caused amongst Dr. Nansen's friends by reports published in an evening paper from the slender testimony of some Samoyedes, that the Kara Sea was unusually hampered by ice this season. The *Nouvelles Geographiques*, it is satisfactory to see, reports on the authority of the captains of the Russian vessels carrying railway material to the Yenesei, and of Captain Wiggins, that the navigation of the Kara Sea was particularly easy this summer, the ice being thin and not compact. The Hammerfest whalers also reported that never within human memory has the sea been so free from ice. At the end of December one vessel saw not a single iceberg between Nova Zemlya and Franz Josef Land. In the Kara Sea the current, which is usually westerly at that season, was this year running north-north-west, at the rate of a mile an hour. The note indicates that Captain Wiggins entertained no doubt of Dr. Nansen having easily reached the New Siberian Islands, which were to be his real starting-point.

IN continuation of the soundings of the English lakes recorded in this column from time to time during the summer, Mr. E. Heawood, assisted by Mr. Shields, has last week made bathymetrical surveys of Ennerdale, Buttermere, and Crummock Waters.

THE annual report of the Tyneside Geographical Society shows that there is now a membership of 1011, and the society generally in a flourishing state. From its headquarters in Newcastle the Tyneside Society extends its operations over a considerable area, and has established a regular branch in the city of Durham.

DR. JOHN MURRAY, of the *Challenger*, has written an elaborate paper on the first voyage of Columbus in relation to the development of oceanography. It is published in the current number of the *Scottish Geographical Magazine*, illustrated by reproductions of a number of ancient maps. Dr. Murray deals incidentally with the origin of the name America, rejecting Horsford's fantastic guess that it came from the name of the Norse explorer Erik the Red, and inclining towards Marcou's theory of its native origin from the Amerrique tribe of Indians in South America. As to Amerigo Vespucci's connection with the name, the author views it as a playful nickname given to him on account of the similarity of his Christian name, which was superseded by *America*, just as he himself is frequently called "Challenger Murray" for the sake of distinction.

THE EROSION OF ROCK-BASINS.

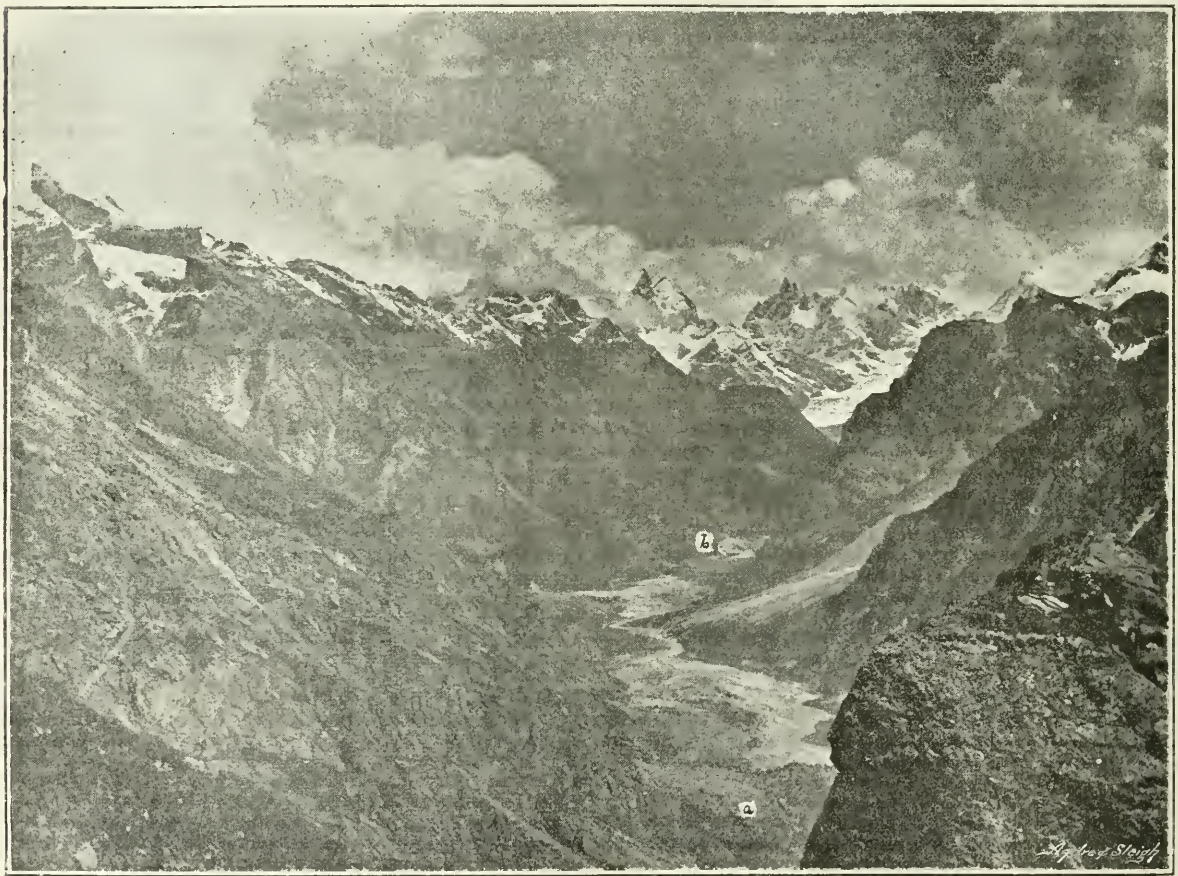
IN a recent letter to NATURE (vol. xlviii. p. 247, July 13, 1893), Sir H. Howorth attacks the views of those extreme glacialists who hold that a glacier is able, by means of the fragments of rock frozen into its under surface, to excavate rock basins: and with justice, so far as the larger basins, such as those of the great Swiss and Italian lakes are concerned, for it has been frequently shown, especially by Prof. Bonney, that such a cause is quite inadequate to account for the excavation of those basins. It seems inconceivable that a glacier which is barely able to move the loose *débris* lying in its path, should be able to plough out hard rocks to any depth whatever below the general valley level. On the other hand, the frequent occurrence of rock basins in regions which are now, or were in former times, subjected to glaciation, is so remarkable, that it appears as though there must be some connection between the two sets of phenomena.

Sir H. Howorth says that, "so far as we know, the mechanical work done by ice is limited to one process. The ice of which glaciers are formed is shod with boulders and with pieces of rock which have fallen down their crevasses. These pieces of rock abrade and polish and scratch the rocky bed in which they lie when they are dragged over it by the moving ice. Without this motion they can of course effect nothing either as burnishers or excavators." But there is another agent of erosion which is only called into play under the peculiar circumstances afforded by glaciers, and one which, I venture to think, is sufficient to account for the formation of these hollows. This is, briefly, the action of the water, derived from the melting of the surface of the glacier. It is now some five years since I had the good fortune to be able to explore some of the large glaciers in the higher regions of the Himalayas, and formed the conclusions which I am now about to put forward; but it seemed to me so likely that they had occurred to others, and probably been dismissed as unsatisfactory—though of this I could not assure myself, as it is long since I have had access to any library in which papers relating to such questions might be found—that I hesitated to publish them. It seems, however, from the remark in Sir H. Howorth's letter, quoted above, that no weight has hitherto been attached to this cause of erosion, however slight it may be, and therefore my observations may possibly be of some value.

Before going into details, I wish to draw attention to one or two facts which have been overlooked by Sir H. Howorth, and which have an important bearing on the discussion. In the first place, whatever be the cause of motion, it is an undoubted

fact that the lower portions of large glaciers do move over level or nearly level ground, and that for considerable distances. Whether the bottom layers of the glacier move at all under such circumstances does not matter much, but that the surface layers move is proved by the manner in which stones are carried down and deposited in a moraine often several miles distant from the foot of the steep slopes at the head of the valley. I am inclined to think that the amount of plasticity attributed to ice, founded on laboratory experiments, has been considerably underrated, and that under the conditions in which it exists in a large glacier it does actually flow, though very slowly, like a viscous body. Why gravity should cease to do any work on the ice, when it rests on a level surface, as Sir H. Howorth states, I cannot see, and when we consider the enormous thickness and weight of ice in a large glacier, there seems nothing strange in its spreading out or flowing in the only direction in which motion posits, the stream which rushes out from beneath the glacier *is* unable to cut down into the solid rock. Therefore, supposing the end of the glacier to remain at or about the same position for a long period, and allowing for a moment that there is *any* erosion whatever going on beneath the glacier higher up, there is undoubtedly a tendency towards the formation of a hollow, closed at its lower end by a rock barrier.

Having clambered over the masses of moraine matter which conceal the lower end of the glacier, we enter upon a broad expanse of ice comparatively free from boulders. Here the surface of the ice usually lies at a very gentle inclination, and may continue in this manner for several miles, until the foot of the steep snow-covered slopes, riddled with crevasses, forming the third stage alluded to above, is reached. It is to this middle, gently sloping portion of the glacier that I wish especially to draw attention, as it is here that the agent of



Glacier at head of Bhutna Valley, Zanskar Range, Kashmir. *a* Old Moraine; *b*, present termination of glacier.

is possible, if we allow any degree of plasticity whatever. In the second place, that erosion of some kind, and that to a large amount, does go on beneath a glacier is proved by the turbid state of the water which issues from the end of it, and it must be remembered that this turbidity of the water is not occasional like that of a river in flood, but is continuous, or at least is recurrent every twenty-four hours, throughout a great portion of the year.

In ascending one of the larger Himalayan glaciers we notice at least three well-defined stages. First, at the foot of the glacier, and for a considerable distance up, perhaps a mile or more, the ice is almost completely concealed by the burden of moraine stuff brought down from above, which, as the ice melts away, is continually being deposited on the floor of the valley. As a result of the continued renewal of these loose de-

erosion, to which I refer the digging out of the hollows, is alone effective. And it is in such positions—that is, immediately below a point where the inclination of the valley decreases more or less abruptly—that in a formerly glaciated region rock-basins are most commonly found.

The ice in this portion of the glacier is traversed by occasional narrow crevasses, into which the streams, often of considerable size, arising from the melting of the surface ice under a hot Indian sun, plunge sooner or later, carrying down numerous pieces of rock with them. Even if the crevasse does not originally extend to the bottom of the glacier, a shaft must quickly be worn out, so that the falling water is enabled to exert the whole of its force directly on the solid floor of rock. These waterfalls are, of course, well known under the name of "moulin," but I do not think that sufficient weight has been

attached to them as an agent of erosion. They must act like so many gigantic drills upon the rock surface, and dig out hollows similar to those found at the foot of an ordinary waterfall. It may be objected that, when the glacier has retreated, we ought to find, instead of one large hollow, a series of pits corresponding to the position of each moulin; but here the peculiar conditions afforded by the presence of the ice come into play. Any particular moulin never keeps the same position for any length of time, not only because a new crevasse may open at any point in the course of the stream, but also because the water is continually cutting back the edge of the fall, as in an ordinary waterfall, but much more quickly. Thus the drills, in course of time, work backwards and forwards over the whole of the area occupied by this portion of the glacier. Indeed, their action may be compared to that of a rapidly revolving drill moved slowly over the surface of a piece of wood, which would ultimately be cut out to any desired depth, or to the action of a sand-blast directed on a piece of plate-glass.

It may be noted that none of the streams find their way down the glacier as far as the mass of moraine matter near its lower end, so that they can have no effect on the rock barrier, which, as I have pointed out, has a tendency to form beneath that portion of the glacier. Moreover, the majority are swallowed up before they reach the lower third or so of this middle portion of the glacier, and thus the well-known section of the bed of those rock basins which have been attributed to glacial action, deepest near their upper ends, and gradually shallowing lower down, is simply and easily accounted for.

It is a curious fact that, in the Himalayas, true rock basins are of very rare occurrence, although the conditions for their formation on the above hypothesis are conspicuously present. It is not, however, difficult to account for their absence if we consider the enormous amount of *débris* carried down by the Himalayan glaciers as compared with that borne by most European glaciers, to judge from pictures and photographs of the latter. It is only the lower portion of the Himalayan glaciers that is so entirely covered by *débris*, and the difference may be partly due to the fact that the hill-sides above this portion of the glacier are much less protected by ice and snow than in the case of the northern glaciers. On the retreat of the glacier this burden of moraine stuff would be quite sufficient to fill up any hollow that may have been formed beneath it. This is well shown in the accompanying illustration, where there is a well-defined old moraine at *a*, the present termination of the glacier being at *b*. Between these two points stretches an almost level plain, some four or five miles long, in which we should have expected to find a lake, supposing a hollow had been worked out beneath the glacier; but in place of it we find this broad stony plain covered with *débris*, evidently derived from the main glacier and from the side valleys. But suppose the glacier were to advance again, all this loose material would in course of time become frozen into the bottom of it, and carried out. Then if a rapid retreat of the glacier were to occur, leaving no time for the hollow—if any exists—to be filled up again, we might have a lake where the plain now is. Or, the contrast may perhaps be accounted for by a difference in the rate of change of climate since the glacial period, which may have been more slow in these southern latitudes than further north, so that the northern glaciers had not sufficient time during their retreat to fill up the hollows formed beneath them. If, as has been supposed, the extension of the European glaciers was partly due to a diversion of the Gulf Stream, might not the rapid breaking down of the barrier which caused that diversion have given rise to the rapid amelioration of climate required?

It would not, I think, be difficult to carry out a few measurements of the erosion that goes on beneath a glacier, which might throw much light on the question. If one visits the mouth of one of these glaciers early in the morning, the stream which issues from it is seen to be nearly, but never quite, free from sediment. This amount of sediment might, I think, be taken as that due to the rasping action of the ice itself, aided by the rocks frozen into its under surface. As the day proceeds, and the surface of the glacier begins to melt, the volume of water issuing at its foot quickly increases, and at the same time it becomes thick with mud. It would be easy to measure the velocity of the stream, and the amount of sediment at intervals during the day, and from this, knowing the area of the glacier, we could estimate the erosion due respectively to the rasping action of the ice and to the drilling action of the moulins. That the latter would be enormously in excess of the former I have no doubt whatever, and I think that it is worth considering whether this may not be an adequate cause of those hollows which do undoubtedly occur in positions that seem to connect them with a former extension of glaciers.

T. D. LATOUCHE.

CHRONO-PHOTOGRAPHIC STUDY OF THE LOCOMOTION OF ANIMALS.[1]

THE chief interest in the study of organised beings is to look for the similarity which exists between the special conformation of each species, and the particular characters of the functions in this species.

The union of comparative anatomy and physiology is becoming more and more close, and will, without doubt, lead to the discovery of the fundamental laws of morphology—laws by means of which the inspection of an organ will permit us to foresee the particularity of its function.

These relations begin to be comprehensible in the case of the organs of locomotion of vertebrates. The size and length of the muscles, the relative dimensions and form of the bony supports of the members, the extent and the form of the articulating surfaces enable us to infer the character of the movements of mammals; and, on the other hand, the accuracy of these deductions can be proved by controlling them by chrono-photography, which gives the geometrical character of these movements.

Attempts have been made to extend this method of analysing the movements of a number of different animal species by chrono-photography, and they have been successful not only with mammals, but also with birds, reptiles, fishes, molluscs, and arthropods.

It will no doubt be a lengthy enterprise to collect the numerous series of pictures necessary for this comparison, but we have been able to assure ourselves that it is nearly always possible to obtain such pictures by varying the conditions according to the kind of animal studied.

Reptiles, for example, must be put in a kind of circular canal, where they can run at their ease; the chrono-photographic apparatus is placed above the path in which the animal runs, and thus photographs the successive attitudes during the course.

The fish swim in similar troughs filled with clear water, and illuminated underneath, in order that their silhouettes should appear on a clear background. At other times the animal is lighted from above, and thus appears light on a dark background. Similar arrangements are employed for insects. It is not necessary to have here the dark background which served for the study of mammals and birds. The principal difficulty is to ascertain whether the animal under experiment is moving in its normal fashion. With the domestic and tame kinds this is not considerable, but with wild species it requires much patience and many attempts to secure the natural movement.

On comparing some of the types of which chrono-photographic images have been obtained, very interesting analogies are found. Thus, for locomotion on land, as well as in water, it is possible to follow the gradual transitions between simple reptation and the more complicated kinds of locomotion. An eel and an adder put in water, progress in the same way; a wave of lateral inflexion runs continually from the head to the tail of the animal, and the velocity of the retrograde progression of this wave is slightly greater than the rate of movement of the animal itself.

If an eel and an adder are placed on the ground, the manner of reptation is modified in the same way with both species. The undulatory movement has here and there a greater amplitude, and this amplitude increases with the smoothness of the surface on which the animal moves.

With fish, provided they have fins, and with reptiles which have feet, there remains, in general, a more or less pronounced indication of the undulating movements of reptation.

With the dog-fish, for instance, the retrograde wave which goes the length of the body is very pronounced; it is much less with salmon, and exists hardly at all, except at the end of the tail, with fish with thicker bodies.

The retrograde wave during the terrestrial movements of the Gecko is plainly visible, but is less pronounced with the grey lizard and green lizard.

The batrachians present, during the successive phases of

[1] Translation of a communication by M. Marey to the Paris Academy of Sciences.

their evolution, varied types of locomotion, familiar to every one, of which the chrono-photographic analysis is very interesting. The tadpole of the toad, for example, exhibits progression in the first stage by the undulation of the fin, when the feet appear there is a mixed type of locomotion; the tail undulates, and on both sides the posterior members execute the movements of swimming which is usual to them. These movements of the posterior limbs alone remain some time after the tail has disappeared. Of these movements, which resemble so much those of human swimming, one is especially noticeable; in this the anterior limbs do not take any part, and the posterior, after having formed a right angle with the axis of the body, approach each other till they become parallel, then bend and stretch themselves again to begin anew. The movements of the lizard's limbs escape direct observation on account of their rapidity, but on the chrono-photographic images, taken at the rate of forty to fifty a second, one can easily follow the successive movements of the limbs in front and behind. With the grey lizard, as well as the Gecko, the normal pace is that of a trot, that is to say, the limbs move diagonally. The great

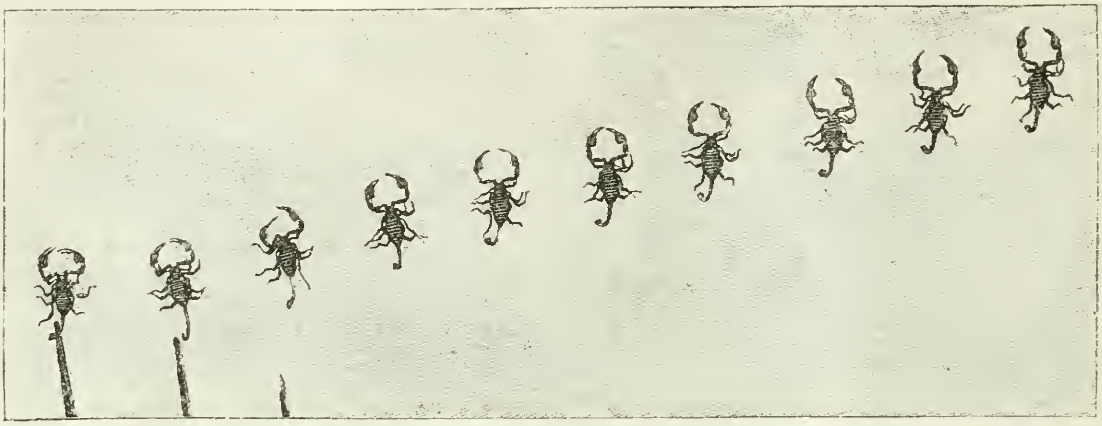


FIG. 1.—Movements of the Scorpion.

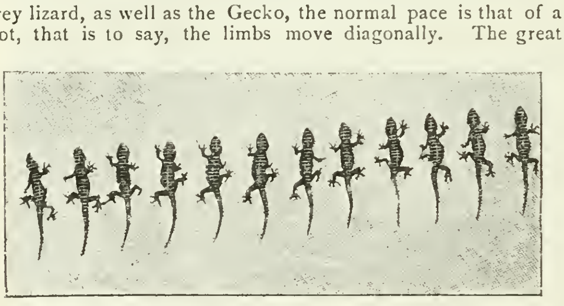

FIG. 2.—Movements of the Gecko.

amplitude of the movements of the limbs, combined with the undulation of the axis of the body, causes the limbs to approach one another very much on one side. and the next instant to separate. The Gecko carries its hind foot nearly under the armpit on the side where the body becomes concave; the instant afterwards, this side becomes convex, the anterior limb advances very much, and the two limbs (the body presenting on this side a convex arc) will be wide apart.

Many other very interesting observations can be made relating to the movements of insects and arachnids.

THE MAN OF MENTONE.[1]

FEW groups of prehistoric finds have provoked a more persistent controversy as to their date and character than those of the Mentone Caves. Were they Palæolithic or Neolithic? Did they belong to the same age as those of the Reindeer Period of the Dordogne? Or should they, on the other hand, be referred to some still living race of men already settled on that Ligurian coast in the "Polished Stone Period"? Other inquirers, again, have sought a third alternative, and referred them to an intermediate period, to which the name "Miolithic," or, better, "Mesolithic," has been speculatively given.

In view of these differences of opinion, the discovery in February of last year of fresh human remains in one of these grottoes associated with relics that throw a clearer light on the culture and surroundings of those deposited with them than any hitherto discovered there, has naturally created considerable interest.

The caves in which these discoveries have been made are formed in the sea-face of the promontory of lower cretaceous limestone that rises just across the Italian frontier on the Ventimiglia side of Mentone, and which, from its red bastions, is locally known as Baoussé Roussé, or, in its Tuscan shape, Balzi Rossi. As early as 1858 the Swiss geologist, M. Forel, had obtained from a superficial layer of one of these caves various animal bones associated with implements. Subsequently Mr. Moggridge dug a section in the grotto known as the Barma dou Cavillou, revealing five floors "formed in the earth by long-continued trampling," with traces of a hearth in the centre of each, and around flint flakes, axes, hammer-stones, and bones of animals. The animal bones were, however, of existing species, and this evidence clearly pointed to Neolithic habitation. But later, M. Rivière, whose patient exploration of these caverns deserves our warm recognition, whatever may be thought of the conclusions drawn by him, unearthed in the same cave, only a foot or two from the point where Mr. Moggridge's excavations had ceased, the perfect skeleton of a man. The skeleton lay on its left side in the attitude of sleep. A stone lay beneath its head and another behind the loins. An ornament composed of bored shells—which may recall the trochus-studded nets still worn by Venetian peasants—was found adhering to the skull, their adherence being due to a ferruginous substance, fragments of which lay near, and which gave a ruddy colour to the whole. Evidently this ochreous substance had been used by the departed in his life-time to paint his face and body, and the whole character of the deposit clearly points to careful interment. From the discovery of bones of extinct animals mixed with the ashes in the overlying stratum, M. Rivière concluded nevertheless that the skeleton was palæolithic.

The fact that the skeleton of the Barma dou Cavillou was undoubtedly embedded amongst Quaternary remains lent some weight to M. Rivière's opinion, and his view of the matter found acceptance from such competent judges as Mr. Pengelly and others. But the presence of the Neolithic hearths, noted by Mr. Moggridge, in an adjacent part of the cave, combined with other circumstances, led M. De Mortillet and Prof. Boyd Dawkins from the first to take a different view. They saw only the evidence of a Neolithic interment in a Palæolithic stratum.

The annexed diagram (Fig. 1) will give an idea of the general conformation of the cave or cleft known as the Barma Grande,

[1] "On the Prehistoric Interments of the Balzi Rossi Caves near Mentone, and their Relation to the Neolithic Cave-Burials of the Finalese." By Arthur J. Evans. A *résumé* of a paper communicated to the Anthropological Institute. (The cuts are kindly lent by the Institute.)

in which the most recent discoveries have been made. From the data that I was able to gather on the spot from quarrymen who at one time or another had taken part in its excavation, the original floor of the cave, at its mouth, over the spot—that is, where the skeletons were found—was 7·50 metres above the stratum in which they lie. But this depth only includes what has been artificially removed from the cave. There are reasons for believing that the deposit had originally been somewhat higher, but that the original level of the floor had been previously lowered by natural agencies.

In 1884 a discovery of a human skeleton had already been made in this cave by Louis Julien, the foreman of the men employed in quarrying the cliff; and so far as the details of this

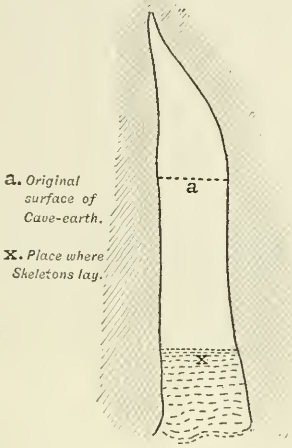

FIG. 1.

find have been preserved, they answer very closely to that of the Barma dou Cavillou. The discovery of 1892 was made close to the spot where the skeleton of 1884 had been unearthed.

Unfortunately, as in the former case, it was not made by a scientific excavator, but by men engaged in quarrying the limestone cliff. I visited the spot shortly afterwards on more than one occasion, but the ornaments and implements had been removed by the owner of the quarry to his house, and there was some difficulty in ascertaining the exact position in which the several relics were discovered.

The subjoined sketch (Fig. 2) will give a fair notion of the position in which the bodies were found. They lay across the present mouth of the cave, with their heads to the east. The outermost skeleton was that of a man apparently well on in life. Unfortunately the skull was broken with a blow of a pick at the moment of discovery, and the length of the skeleton can therefore be only approximately given. From his heel to his shoulder he measured 1·85 metres, so that he was probably at least as tall as the taller of the three adult skeletons found in 1872–1873, which reached the length, according to M. Rivière, of 2 metres. This gigantic frame was somewhat turned to the left, but it lay more on its back than the other two. By his left hand, laid close to his femur, lay a long flint knife (Fig. 3). About the neck and on the skull were remains of ornaments of teeth and bone, fish vertebræ and pierced shells, among them many *nassa neritea*, and on the legs a little below the top of the tibias were two Cypræas.

Immediately behind this lay a skeleton, recognised by Dr. Verneau as that of a woman. It rested on the left side with the knees slightly drawn up, and its right hand almost resting

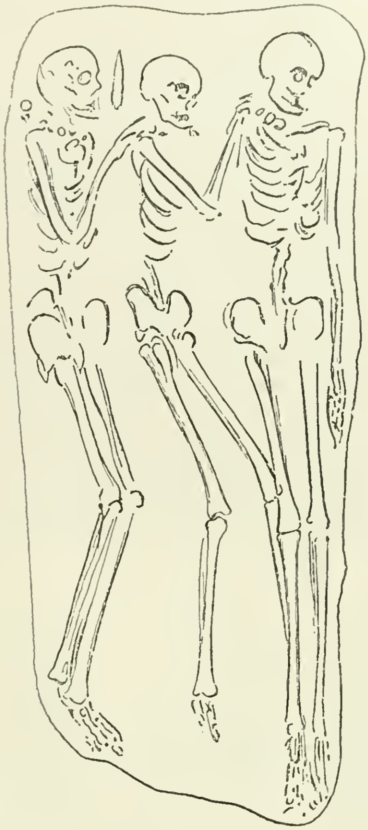

FIG. 2.

on the giant's shoulder. It is said to have held another flint knife. This female skeleton was not so richly decked with ornaments as the other two, the bone and tooth pendants being absent in this case. The third skeleton, of a youth, lay in much the same attitude as the second, with its right hand raised as if to be laid on the shoulder of the individual in front of it. Under or near its head a third flint knife was discovered. Both the two inner skeletons, though of tall stature, were distinctly smaller than the first discovered.

From the position in which the bodies lay it seems natural to conclude that the two smaller individuals here interred were in a position of dependence on the old giant. Amongst the objects found, chiefly, as far as I could gather, about the heads and necks of the skeletons, were remains of necklaces or head ornaments of shell and bone, amongst which may be mentioned bored shells, fish vertebræ, and teeth—apparently canines of

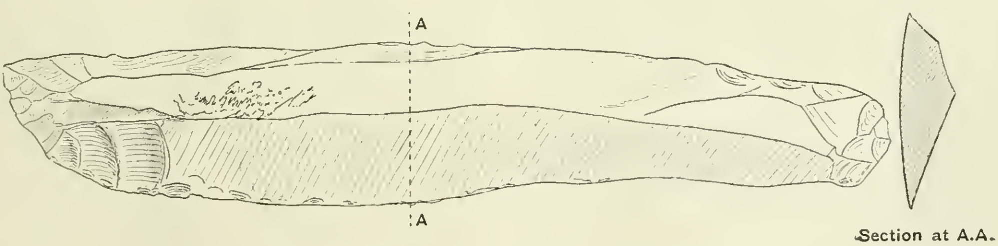

FIG. 3.—Flint knife found with first skeleton. ½ linear (23 × 5 cm.).

deer—which had been much rubbed down and in some cases adorned with incised lines and nicks (Fig. 4). Of the bone ornaments discovered, the most remarkable were some curious objects like double eggs or acorns connected by a common stem (Fig. 6). These, too, were incised in a similar manner. Amongst the bored shells found I was shown specimens of small Cypræa (millepunctata), Cerithium, and a kind of Trochus, and a quantity of *Nassa neritea*—the same shell that formed the head ornament of the skeleton excavated by M. Rivière in the Barma dou Cavillou.

Another interesting correspondence between the present discovery and that of the Barma dou Cavillou was the presence, in the earth about the skeletons, of lumps of a ferruginous substance, which in this, as in the other cave, had partly stained the bones. There can be no doubt that this had been placed with the departed that he might have the wherewithal to paint his face and body for entry into the Spirit World.

On the osteological characteristics of the skeletons I cannot speak as an expert. They have, however, been examined by competent authorities, whose accounts in the main agree. The skulls were decidedly dolichocephalic. The large skull has prominent supra-orbital ridges, the smaller skull has these prominences less marked and is narrower across the frontal bones, but, still, stronger, thicker, and more definitely ridged than the Neolithic skulls of the Finalese. Professor Issel, M. Rivière, Mr. A. V. Jennings, and more recently Dr. Verneau have been independently led to compare the Cro-Magnon skulls—M. Rivière especially laying stress on the curious rectangular orbits. Prof. Issel, in a communication read before the Natural History of Genoa, although himself in favour of the Palæolithic date of the interments, was yet led to the conclusion that the crania and skeletons presented on the whole the same racial

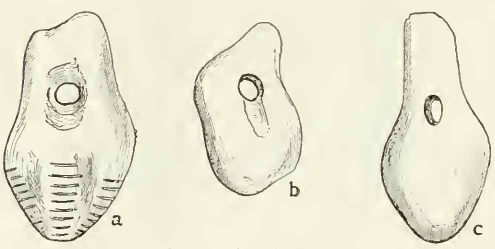

FIG. 4.—Deer's-tooth pendants.

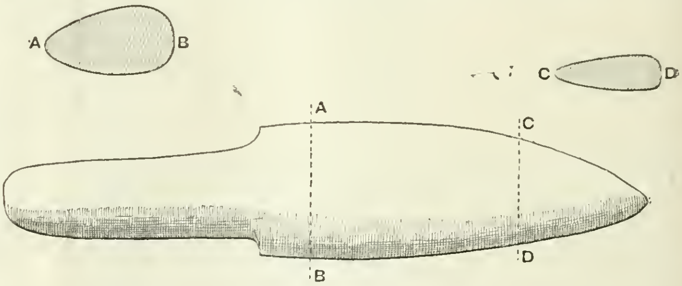

FIG. 5.—Bone arrow-head.

characteristics as the undoubtedly Neolithic skeletons of the caves of the Finalese further along the same Ligurian coast.

The great depth at which these skeletons occurred, and the absence, in this whole group of finds, of pottery, polished stone implements, and the bones of domestic animals, must be certainly taken to show that they date from a considerably earlier period than the Neolithic interments of the Finalese caves—in which all these elements of more developed culture are abundantly represented.

But are we therefore to conclude that the Balzi Rossi remains are of Palæolithic date?

It seems to me that there are other circumstances to be considered in connection with these latter finds, which do not admit of such a conclusion—unless, indeed, the word "Palæolithic" is to be given a sense different from its usual acceptation.

When we come to examine the views as to the extreme antiquity of the instruments, such as M. Rivière has not hesitated to put forward in the most unqualified manner, we find, in fact, a curious illustration of the danger of proving too much. The skeletons lie in all cases beneath a vast mass of cave-earth in which the remains of extinct animals are undoubtedly associated with implements of flint and bone that may justly be regarded as the work of Palæolithic man. Therefore we are told the interments themselves must belong to the same age. Long flint knives such as those discovered, may, it is true, find parallels in some of the later Palæolithic caves such as that of La Madeleine, though like implements were also in common use in Neolithic times. But the argument invoked by M. Rivière leads us to consequences far beyond this. In the cave-earth of the overlying stratum implements occurred not only of types characteristic of the Magdalenian group, of Solutré, and of Laugerie Haute and Basse, but there were included quartzite and other forms peculiar to the still earlier art of Le Moustier. In the same way the bones of extinct animals found lead us on this showing to the conclusion that the "Man of Mentone" dated back to the days of the earliest group of Pleistocene mammals. But as a matter of fact among several cases of bones of animals found in the immediate neighbourhood of the skeletons that have been recently examined all are of recent species, and not a single characteristic Quaternary form occurred. It is to be observed, moreover, that the mere fact that these were interments, implying as it does previous excavation, makes the appearance of Pleistocene remains, and even Palæolithic implements at higher levels in the cave-earth, of no value for determining the age of the skeletons.

The careful laying out of the dead in the attitude of sleep with his flint knife in his hand, his necklace and head ornaments, and the ochre beside him wherewith to paint his face and body in the other world—all this shows a development in religious custom which has hitherto in no single well-authenticated instance been carried back to Palæolithic times. It is characteristically "Neolithic." We may go further and say that the special forms of sepulture discovered here fit on in a suggestive way to the burial rites still practised at a later date on this same coast by the Neolithic people of the Finalese. There too we find the body laid out in the same attitude of sleep, with the legs partially drawn up, an attitude which, as distinguished from the still more contracted posture of the Northern races in primæval times, we may perhaps venture to regard as characteristic of a less severe climate, and the less habitual necessity for drawing up the legs under the shelter of whatever served them as a mantle. There too we find the same bored shells and teeth hung round the neck, and the same ferruginous substance laid beside the departed to deck his person in the Spirit World; there too flint and bone objects (some of these latter of very similar forms) were placed ready to his hand. In the caves of Balzi Rossi, however, the skeletons were at most propped up or pillowed by large stones; in the Finale interments, such as those of the grotto of the Arene Candide, we find, in the case of the adults, stones placed round and over the skeletons so as to form a rude cist, though the children were still simply buried in the cave-earth. In these later interments, moreover, the polished axes and pottery placed beside the dead as well as the remains of domesticated animals attest the higher stage of culture amidst which they had lived. Still the points of similarity in the sepulchral rites practised in both groups are unmistakable. And in view of these points of resemblance the conclusion arrived at by Prof. Issel, that the Balzi Rossi skeletons, in spite of some more primitive characteristics, belong essentially to the same race as the skeletons of Finalmarina, gains additional force.

The bone implements supply us with some fresh points of relationship. The bored pendants, formed of canines of deer much worn down, found with the skeletons both in the Barma Grande and the Barma dou Cavillou are identical even to their notched decorations with ornaments of the same kind found by Prof. Issel in the Caverna delle Arene Candide near Finalmarina associated with undoubtedly Neolithic remains. Identical pendants have also been found in the Neolithic deposit of the Grotta di Sant' Elia in Sardinia. It is to be observed that very similar deer's tooth ornaments, though without the notches, were found in the caves of La Madeleine, Laugerie Basse and Les Eyzies, where they are ascribed to the Reindeer Period. A stumpy bone punch also found near the Barma Grande skeletons, in the possession of Mr. A. V. Jennings, is of the same type as a bone implement from the excavations oft he Neolithic deposit

in the grotto of the Arene Candide. Another very close parallel is afforded by the cusped bone instrument represented (Fig. 5), which the Rev. J. E. Somerville, of Mentone, obtained from the neighbourhood of one of the last discovered skeletons of the Barma Grande. Though blunter and thicker, it greatly resembles some of the bone arrow-heads from the Neolithic burial-place in the Arene Candide cave.

Of all the bone objects, however, discovered with the present interments the most interesting are those already referred to as

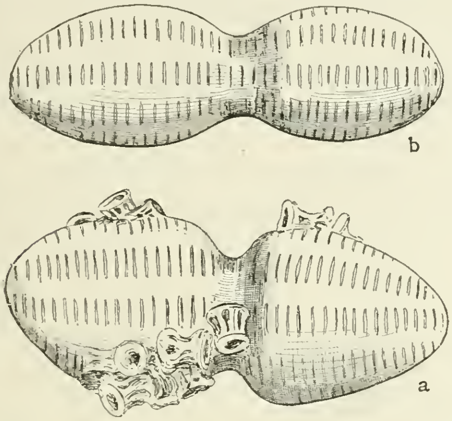

FIG. 6.—Bone ornaments, (*a*) with fish-vertebræ adhering.

resembling two small eggs, or acorns, with their big ends united with a connecting stem. The bossy part of these ornaments was decorated with rows of parallel lines running up the sides like the rungs of so many ladders. Seven or eight of these are said to have occurred in all, but, like other relics found, most of them have since disappeared. The shape of different specimens varied slightly, some being more elongated than others.

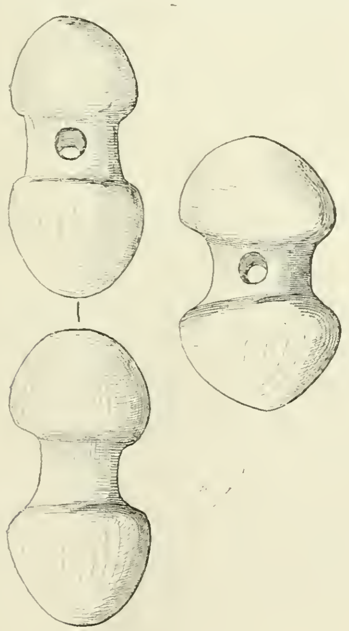

FIG. 7.—Scandinavian amber beads.

But what at once struck me on seeing these objects was the great resemblance they presented to certain amber ornaments discovered with early Neolithic skeletons in the galleried tombs of Scandinavia and North Germany. The objects in question are certain double-bossed ornaments of amber, in Scandinavia generally known as "hammer-shaped" beads, and which, from their supposed resemblance to the stone-hammers of the same period, have been by many supposed to have been worn as amulets. (Fig. 7.)

The geometrical system of ornamentation
ments from the Mentone Cave seems to be fo
on bone and horn relics of the "Reindee
other hand, like the bone ornaments themse
occurs, it presents the closest analogy to a style of
very characteristic of the Later Stone Age in Northern Euro

The conclusion, then, to which we are led by these converging lines of evidence is that the interments of the Barma Grande and the other caves of the Balzi Rossi cliffs, though embedded in a Palæolithic stratum, are themselves of Neolithic date. On the other hand, however, the entire absence of pottery, of polished implements, of remains of domestic animals, as compared with the abundance of all these features in the Neolithic interments of the Finale Caves further up the same Ligurian coast, is on any showing a most remarkable phenomenon. A greater degree of petrification is also observable in the bone and other objects discovered. *In all probability, therefore, we have here to deal with an earlier Neolithic stratum than any of which we have hitherto possessed authentic records.* If the evidence of these Balzi Rossi interments is to count for anything, it must henceforth be recognised that a race representing the essential features of the later population of the polished Stone Age was already settled on the Ligurian shores of the Mediterranean at a time when many of the civilised arts, which have hitherto been considered as the original possession of Neolithic Man on his first appearance in Europe, were unknown. It will no longer be allowable to say that these supposed immigrants from Asia brought with them at their first coming certain domestic animals, and had already attained a knowledge of the potter's art, and of the polishing of stone weapons. And, if this is the case, something at least will have been done towards bridging the gap between the earlier and later Stone Age in Europe. Till such time, however, as remains of extinct animals are found in such association with human interments as to prove their contemporaneity we must still allow for a vast interval of years between the latest remains of the "Reindeer Period" and interments, such as those of the Mentone Caves.

The racial characteristics of the skeletons of the Balzi Rossi, while linking them at one end with the later Neolithic occupants of the Finalese, show that they had essentially the same physical type as the early skeletons found in Cro-Magnon Cave with very similar ornaments of bored shells and teeth. The same features occur again in the skeletons from the Neolithic grotto of the Homme Mort, in Lozère, and in some of the French dolmens, as that of Vignettes. The type recurs East of the Apennines and in Central Italy, Sicily, and Sardinia; and the field of comparison extends to Southern Spain and the Canaries.

The physical connection with the Dolmen people derives additional interest from the comparisons established between the bone ornaments found with the Barma Grande skeletons and the amber hammer-beads of the Scandinavian Gallery Graves, and the decorative system of the pottery found in the same. It looks as if in the polished Stone Age the Neolithic settlers in the North of Europe had transferred to the new materials, such as amber and earthenware, forms and ornamentation which had already been an ancient possession of a race settled on European soil in still more primitive times.

Two shells found with the Balzi Rossi interments, *Pecten maximus* and *Cypræa millepunctata*, seem to point to Atlantic connexions. In the later Neolithic interments of the Finalese, on the other hand, which may represent the same race in a more advanced stage of development, we see new influences coming in from a very different direction. Some of the shells found with these seem to have been derived from the Southern Mediterranean, and one, the *Mitra oleacea*, found by Prof. Issel in Caverna della Arene Candide, must have made its way by some primitive line of intertribal barter from the Indian Ocean.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. Theodore J Pocock, of Corpus Christi College, has been elected to the Burdett-Coutts Scholarship in Geology. For the Merton Biological Fellowship a strong list of candidates is reported, including among others Messrs. F. E. Beddard, M. S. Pembrey, E. A. Minchin, P. C. Mitchell, and R. T. Günther.

As the result of a memorial addressed to them by the demonstrators in the various departments of Natural Science, the Hebdomedal Council have appointed a committee, consisting of Mr. T. Raleigh, of All Souls, and Mr. T. H. Grose, of Queen's College, to inquire into the position and status of the demonstrators at the museum.

Cambridge.—Dr. Forsyth has been appointed chairman of the Examiners for the Mathematical Tripos, Part II., and Mr. Welsh, of Jesus College, for Part I.

Prof. Ramsay, of University College, London, has been elected Examiner in Chemistry for the Natural Sciences Tripos.

At St. John's College, Mr. E. W. Macbride, Hutchinson Research Student, and University Demonstrator in Animal Morphology, has been elected to a Fellowship. Mr. MacBride took a first class in both parts of the Natural Sciences Tripos (zoology and botany) in 1890–91, and is the author of various morphological papers based on researches conducted in Cambridge and at the Zoological Station at Naples. He has been President of the Union Society, and is well known as a vigorous debater. At the competition for Fellowships on this occasion there were no less than seven candidates in Natural Science, who had all taken first class honours in the Tripos as students of St. John's.

SCIENTIFIC SERIALS.

Wiedemann's Annalen der Physik und Chemie, No. 10.—On air vibrations, by A. Raps. The changes of density at the nodes of open and closed organ pipes were recorded by allowing a beam of strong white light to fall upon the mirror of a Jamin interference refractor. One of the reflected beams was sent through a pipe at the node, the other through a box containing undisturbed air. After reunion by the second mirror, these two beams gave rise to interference fringes, which were displaced during the changes of density accompanying the sound of the pipe. A section across these fringes, consisting of bright and dark points, was received upon a revolving drum carrying sensitive paper, and the oscillation of the points gave rise to a series of curves representing the sound vibrations with very fair accuracy. A series of eighty-eight photographs are reproduced, which give valuable hints concerning the structure of the various notes, and also some vowels and consonants produced in the open air.—Luminous phenomena in electrode-less vacuum tubes under the influence of rapidly alternating electric fields, by H. Ebert and E. Wiedemann. This paper, a sequel to the general investigation published in No. 9, deals with the details of the phenomena observed between the condenser plates of a Lecher wire system in the case of spheres, cylinders of various lengths, conaxial double cylinders, and glass parallelepipeds with plane ends.—Heat of dissociation in electro-chemical theory, by H. Ebert. Calculations based upon heat of dissociation and electrolytic work show that the forces of chemical affinity are chiefly of an electric nature, that the forces due to "valency-charges" are the most powerful of any atomic forces, and that any additional chemical forces are, in comparison, infinitesimal.—Equipotential lines and magnetic lines of force, by E. von Lommel. Some further photographic tracings of these lines are given, and their bearing upon the Hall effect is discussed.—Objective representation of interference phenomena in spectrum colours, by the same author. Simple arrangements are described for exhibiting Newton's rings, gypsum fringes, convergent polarised light phenomena, and fringes produced by the rotation of the plane of polarisation in quartz prisms, upon a screen. For Newton's rings the light from the heliostat is reflected by a colour plate, and falls upon a lens which produces an image of the sun at its focus. By placing a slit at this focus and a prism between slit and lens, the rings in all the spectrum colours may be thrown upon the screen by shifting the slit.—Papers by Kayser and Runge, P. Czermak, and R. J. Holland have already been mentioned.

The pages of the *Botanical Gazette* for September contain but little except reports of the proceedings of the Botanical Section of the Madison meeting of the American Association for the Advancement of Science, of the Madison meeting of the Botanical Club, and of the Madison Botanical Congress. That for October contains several important papers:—On the fructification of *Juniperus*, by Mr. J. C. Jack, who states that in America the fruit of the English species of juniper does not mature until the autumn of the third year after blossoming; on the development of the embryo-sac of *Acer rubrum*, by Mr. D. E. Mottier; on the achenial hairs of *Compositæ*, by Miss M. A. Nichols; and on the bacterial flora of the Atlantic Ocean in the vicinity of Woods Holl, Mass., by Mr. H. L. Russell. The results obtained by the author accord in a general way with those previously made in the Mediterranean. While the water and underlying sea-flow are filled with bacterial life, they are by no means in an entirely quiescent condition. Both water and mud are peopled with micro-organisms which are undergoing their cycle of development here as elsewhere.

The Nos. of the *Journal of Botany* for October and November are almost entirely occupied by papers on local and descriptive botany, including the completion of Mr. E. G. Baker's synopsis of Geneva and species of *Malveæ*, and a sketch of the botany of Ireland, by Mr. A. G. More.

The summer number of the *Jahrbuch* (Austrian Geological Survey) contains contributions by Drs. Emil Tietze, von Wöhrmann, Bittner, Skuphos, and others. Dr. Emil Tietze writes on the "Geology of the Ostrau District." Great hopes were raised in this neighbourhood by the discovery of coal near Wagstadt, in the Upper Oder valley, but Dr. Tietze informs us that the coal occurs only locally and in mere fragments. With regard to the age of the Ostrau beds, he argues that they should be grouped with the *upper* and not with the *lower* carboniferous series. They rest unconformably on the Culm grits and shales and are conformably succeeded by the Schatzlar beds, a deposit closely resembling the Ostrau beds in general character. Another paper by Dr. Tietze discusses the prospects of the salt industry in East Galicia.—Baron v. Wöhrmann contributes an article on the "Systematic Position of the Trigonidæ and the Descent of the Nayadidæ." He shows that both the Trigonidæ and the Nayadidæ have true heterodont hinges, and that therefore the classification into schizodont and heterodont bivalves suggested by Neumayr cannot be carried out. Taking the fresh-water bivalve Unio as type-form of the Nayadidæ, v. Wöhrmann traces the phylogenetic relationship of this family with the genus Trigonodus (Up. Triassic shore deposits), and through Trigonodus with the ancient ancestral type, Myophoria (Devonian to Rhætic).—Dr. Theodor Skuphos completes his survey of the Partnach beds in the Northern Alps. He found in the Vorarlberg deposits of this age a new fossil Saurian, which he names *Partanosaurus Zitteli*. Dr. Skuphos thinks it probable that this Saurian is identical with certain remains found in extra-alpine deposits of Upper Muschelkalk age in Würtemberg.

SOCIETIES AND ACADEMIES.

London.

Physical Society, October 27.—Prof. J. Perry, F.R.S., vice-president, in the chair.—Mr. E. C. Rimington read a paper "On the Behaviour of an Air-Core Transformer when the Frequency is Below a certain Critical Value." Taking the ordinary differential equations for two circuits having self and mutual induction, and assuming sinusoidal E.M.F.'s and constant coefficients, the author shows that although the difference of phase between the primary P.D. and primary current is always diminished on closing the secondary circuit, yet under certain circumstances this closing increases the impedance of the primary. With constant P.D. this means that closing the secondary decreases the primary current, a phenomenon not usually observed. The critical conditions necessary for increased impedance are fully worked out in the paper, as well as those under which this increase becomes a maximum. In the case of two identical coils with no magnetic leakage, the critical value of α ($\alpha = \frac{pL}{r_1}$ where $p = 2\pi$ times the frequency, L the inductance of the primary, and r_1 its resistance) is $\sqrt{2}$, whilst that to give maximum impedance is $\frac{1}{\sqrt{2}}$. The maximum increase possible is $15\frac{1}{2}$ per cent. The corresponding values are given for various amounts of magnetic leakage in tabular form, and curves were exhibited at the meeting showing how the impedance, current, power, and magnetising effect vary for different values of α. To test his conclusions the author made experiments on two coils close together, the observed increase in impedance amounting to 3·2 per cent. In addition to the analytical

investigation, the subject is treated geometrically at considerable length. Prof. Minchin showed that the impedances might be represented by two hyperbolas, having p^2 as abcissæ and the squares of the impedances as ordinates. These could be readily constructed from the data given. A line representing the primary inductance drawn on the same diagram intersects one hyperbola, showing that the impedance has always a maximum value. By a simple construction the phase angle between the primary and secondary currents could be determined for any given conditions. Dr. Sumpner observed that increased impedance on closing the secondary necessarily meant a decrease in the lag of the primary current behind the primary P.D. Mr. Blakesley was pleased to see the geometrical method of such service, and thought it much simpler than the analytical one. The reason why increased impedance on closing the secondary of ordinary transformers had not been noticed was because their lag angles were very large. In a figure published some years ago to represent the actions of transformers, the angles he had chosen were such as would make the primary impedance increase on closing the secondary. Giving an expression connecting the primary currents on open and closed secondary respectively, he now showed that to get increased impedance, the sum of the lag angles in primary and secondary must exceed 90°. To get large power in the secondary the primary lag should be nearly 90°, and the secondary about 45°. He also pointed out that some of the figures in the paper might be simplified considerably. Prof. Perry said he had long had the impression that if a sufficiently small current were taken from the secondary, increased impedance would be observable in all cases, and he quoted some numbers he had given in the *Phil. Mag.* for 1891, showing a decided increase. Mr. Rimington, in reply, said he was not aware that the effect he had now brought forward had been observed previously. The result was completely worked out analytically before using geometrical methods.—Mr. W. B. Croft showed "Two lecture-room experiments." One, on "The Rings and Brushes in Crystals," was performed by very simple apparatus in two ways. In the first, a bundle of glass plates was used as a polariser, and a Nicol prism as analyser. When a Nicol could not be conveniently obtained, a glass plate could be used as a reflecting analyser. For a convergent system two glass card-counters were used, the crystal being placed between them. Very good results were produced by this simple apparatus. In the second arrangement the crystal was placed on the eye-piece of a microscope (whose objective was removed), and covered by a tourmaline. On reflecting light up the tube by means of a piece of glass held at the proper angle excellent results were obtained. Another experiment, on "Electric Radiation in Copper Filings," was similar to those described by Dr. Dawson Turner at the Edinburgh meeting of the British Association. A battery, galvanometer, and glass tube containing copper filings were joined in series. Under ordinary circumstances no current passed, but immediately an electric spark was produced by an electric machine many feet away, the galvanometer was violently deflected, and remained so until the tube was tapped. On trying different materials, aluminium and copper seemed about equal, but iron not so good; carbon allowed the current to pass always. Prof. Minchin said the phenomena were strikingly like those exhibited by his "impulsion cells," for the moment a spark passed, even at a distance of 130 feet, they became sensitive to light. Very minute sparks were capable of producing the change, but by adding capacity to the sparking circuit the effect could be greatly modified. Replying to a question from Mr. Rimington, he said the change was due to electromagnetic vibrations, and not to light emitted by the sparks. Mr. Blakesley inquired if lengthening the sparks produced greater effect on the copper filings. Mr. Lucas asked if the resistance of a tube ever became infinite again if left for a long time. In reply, Mr. Croft said the current sometimes passed before the spark actually occurred between the knobs. He had not left tubes for very long, and had not found the resistance reappear without tapping.

Royal Microscopical Society, October 18.—A. D. Michael, President, in the chair.—Mr. J. G. Grenfell described some marine diatoms, recently found at Plymouth, belonging to the genera *Melosira* and *Surirella*, which were of interest owing to the presence of pseudopodia. Mr. A. W. Bennett objected to the term pseudopodia being applied to these processes unless it could be shown that they were actual prolongations of the internal protoplasm. Mr. T. Comber said that Prof. Grunow was of the opinion that the processes were spines. —Mr. E. M. Nelson exhibited and described a new model of a microscope by Messrs. Watson.—Mr. F. Chapman read Part V. of his paper "On the Foraminifera of the Gault of Folkestone."—Prof. Bell gave a *résumé* of a paper by Dr. R. L. Maddox, "On Progressive Phases of *Spirillum volutans*." The author had traced the development of this organism, and had discovered some points which appeared to be entirely new in the history of bacteria.

Paris.

Academy of Sciences, October 30.—M. de Lacaze-Duthiers in the chair.—The grape-vine harvest of 1893 and the produce of the Camargue, by M. Chambrelent. In spite of the severe drought the vineyards of the Gironde have given the richest yield in the century. This has been due to a unique combination of favourable circumstances during their development. The facility with which they withstood the drought may be attributed to the fact that vine-leaves have a peculiar power of absorbing dew, which has been very abundant. This year has also witnessed the earliest date of harvest known in the century. In 1822 it took place on August 31, whilst this year it was eight days earlier. The quality of the harvest, which improves with the quantity, may be expected to prove very good.—On the application of sound vibrations to the analysis of mixtures of two gases of different densities, by M. E. Hardy. The apparatus, called the formenephone, consists of two organ pipes, one of which is filled with pure air, the other containing the mixture of gases to be analysed. The pipes are of the same dimensions, and give the same note when blown under the same circumstances. If one of them is filled with air containing 1 per cent. of formene, the unison is disturbed and one beat is heard every three seconds. With 2 per cent. there are three beats in two seconds, with 3 per cent. two beats per second, and so on. Similar results may be obtained with carbonic acid as an impurity. The figures given apply to pipes sounding C_4. For mixtures whose density closely approaches that of air C_5 is more suitable. Each determination is finished in a few seconds. The apparatus is well suited to the determination of the amount of fire-damp in mines.—Observations of Comet Brooks (1893, Oct. 16) made at the Algiers Observatory by MM. Rambaud and Sy.—Observations of the sun made at the Lyon Observatory (Brunner equatorial) during the first half of 1893, by M. J. Guillaume. This is a summary of the observations made of sunspots and faculæ, with particulars of their positions and areas.—On a new theorem of mechanics, by M. N. Seiliger.—On carboxyl derivatives of dimethylaniline (dimethylamidobenzoic acid) by M. Charles Lauth.—On the baking temperature of bread, by M. Aimé Girard. Numerous experiments have proved that 101° C. is the normal temperature in the interior of bread and biscuit during baking if the product is to be satisfactory.—Study of the reproduction of wasps, by M. Paul Marchal. Careful observations of the physiological function of the workers, miscalled neuters, of a common wasps' nest have proved parthenogenetric reproduction by the workers, without the cooperation of the males, and the exclusively male sex of the individuals thus produced. It appears that there is a division of labour between the queen, who produces mainly females and workers, and the workers themselves, which are only capable of producing males.—On the localisation of the active principles in *Tropæolum*, by M. Léon Guignard. In the Tropæolum family, all the organs enclose myrosine, localised in cells distinct from those which contain the glucoside, which it decomposes to produce the essence. The latter does not pre-exist in the tissues and cannot be formed without the intervention of the ferment. The family shows in this respect a complete analogy with the Crucifers and Capparideæ.—On the existence of gismondine in the geodes of a basalt of the environs of Saint-Agrève (Ardèche), by M. Ferdinand Gonnard.—Fractures of the coal measures of southern Chili, by M. A. E. Noguès. In the lignite region extending from the Bay of Talcahuano to Lebu, there is found a large fault running from east to west, which it is proposed to call the Lebu-fault. To the north of this fault the strata incline towards the west; to the south, they incline towards the east. Between San Rosendo and Lebu may be traced a system of parallel north-to-south faults which have affected the older strata; a system o parallel east-to-west faults, which have dislocated the arenaceous lignite territory; and a system of secondary faults, which have brought about changes of level in this same formation.—General

characters of the *bogheads* produced by Algæ, by MM. C. E. Bertrand and B. Renault. A study of the *boghead* of Autun, the kerosene shale of Australia, and the brown torbanite of Scotland show that these deposits are due to the thalli of a single species of alga, that of Autun containing *Pila bibractensis*, the kerosene shale Reinschia australis, and the Torbanite another *Pila*.

BERLIN.

Meteorological Society, October 10.—Prof. von Bezold, President, in the chair.—Prof. Hellmann spoke on the frequency of halo phenomena, after having first described their typical features and their causation by reflection and refraction from hexagonal ice-prisms. From observations at Upsala extending over seven years he had ascertained that the 22° halo is most frequently observed, then mock suns and moons, then the 46° halo, and least frequently the vertical pillars of light. On the whole the phenomena are five times more frequent in connection with the sun than with the moon. During the course of a year the phenomena follow a regular course; solar-halos are at a maximum in May and a minimum in December, whereas lunar-halos are at a maximum in December and a minimum in May. If snow-crystals were equally plentiful in the air at all periods of the year, then solar-halos would be most frequently seen in June, at the time when the sun is above the horizon for the longest period on each day. But inasmuch as there are fewer snow-crystals in the air in the summer, the maximum is put back to May. The maximum for lunar-halos occurs when the nights are longest and there are most snow-crystals in the air. Statistics from the polar stations for 1882–83 show that only solar phenomena occur during the period of midnight sun, and only lunar phenomena during the polar night, their frequency being solely dependent on the occurrence of clouds. An account was given of a stroke of lightning in Heligoland which had smitten two persons near the railroad, killing one and stunning the other. Photographs were exhibited of the latter as showing the characteristic marks on the arm, chest, abdomen, and legs. After a member of the Society had suggested a new method of estimating clouds—which, however, requires further working out and testing—the President drew attention to wave-clouds as described by Von Helmholtz in his most recent theoretical work on the dynamics of the atmosphere. They occur when two layers of air travelling with different velocities pass one over the other, in which case waves are formed and clouds at the junction of the layers. These clouds are then drawn out into long strips, formerly called polar-bands. They occur not only in the layers of cirrus clouds, but also at lower levels. A wish was expressed that these clouds might be photographed.

Physical Society, October 20.—Prof. Kundt, President, in the chair.—Dr. Raps gave an account of his work on the photography of aërial vibrations. The method is based on the use of a Jamin's refractometer, which produces interference phenomena by means of reflection and refraction of a ray of light at the surfaces of two parallel glass plates. When the air between the two plates is transmitting waves of condensation and rarefaction, the interference bands are displaced, and if they fall on a slit behind which a sensitized paper is kept in motion on a drum, the waves of aërial vibration may be recorded. The experiments were first made on a closed organ-pipe, near whose upper end were two openings facing each other but closed with glass. Through these the two rays of light passed before they were made to interfere. When the pipe was gently blown, sine curves alone were obtained, corresponding to the fundamental note of the pipe. As the pressure was increased, the overtones became more and more prominent, until at last they alone determined the shape of the curve. Further experiments were made with closed reed pipes, after it had been ascertained that the tongue of the reed vibrates like a pendulum. The phenomena were the same as in the first case. Experiments with open pipes were found to be much more difficult, but even in this case good photographs of the vibrations were obtained. Dr. Raps had also been able, by the same method, to photograph the vibrations resulting from the singing of vowels, and to show that definite harmonic overtones are characteristic of each vowel. Similarly photographs had been taken of the vibrations due to a hunting-horn. Dr. Raps further exhibited an Ampère apparatus for lecture purposes, in which the current was supplied by means of metallic instead of mercury contacts.

Physiological Society, October 27.—Prof. du Bois Reymond, President, in the chair.—Dr. Lewin gave an account of researches on the physiology of the ureter, carried out in conjunction with Dr. Goldschmidt. These had shown that the entry of urine into the upper end of the ureter is due to pressure exerted by the kidney; that the peristaltic waves of contraction of the ureter either pass right down to the bladder, or occasionally stop short in their course along the ureter; that the point of entry of the ureter into the bladder is possessed of a sphincter, but that notwithstanding this it is occasionally possible for fluid to be driven back out of the bladder into the ureter.—Prof. Senator spoke briefly about the experiments he made some seventeen years ago, on the results of varnishing the skin in men, defending their validity, and the conclusion that varnishing does not affect the health, against objections which had recently been brought forward.—Dr. Cohnstein described experiments on the influence of diffusive processes on transudation. When salt solutions were allowed to flow under a constant pressure through a ureter or jugular vein surrounded by fluid, it was found that the amount of salt passing through into the outer fluid increased with the pressure on the latter. Similarly a solution of egg-albumen diffused more copiously into an external fluid than could be observed when it was forced by filtration into a space filled with air; but the amount of albumen which passed through was independent of the external pressure. This diffusion must play a very important part in the transudation of fluid from the blood-vessels, and in the tissue-cells of the living organism, and may suffice to explain many as yet incomprehensible phenomena.

ROMANES ON WEISMANN.

An Examination of Weismannism. By G. J. Romanes, M.A., LL.D., F.R.S. (London: Longmans, Green, and Co., 1893.)

DR. ROMANES is a most competent hurler of hard words, and in this volume is concerned at least as much to convince the reader that Weismann is an uncertain guide as to be to him himself a certain guide. In the preface he states his intention to publish his criticisms "in separate form and in comparatively small editions, so that further chapters may be added with as much celerity as Prof. Weismann may hereafter produce his successive works." In the text, writing of the relations between the views of Galton and Weismann, he talks of those immense reaches of deductive speculation, which, in his opinion, merely "disfigure the republication of stirp under the name of germ-plasm" (!) The mention of certain occurrences which are believed in by Dr. Romanes, but the admission of which he considers illogical on the part of Weismann, "seemed attributable to mere carelessness on the part of their author." Another consideration is "made by Weismann for the sole purpose of saving as much as he can of his previous theory of variation." Another is "an obvious equivoque." The mechanism of heredity is planned out (in Weismann's latest volume) "in such minuteness of detail and assurance of accuracy that one is reminded of that which is given by Dante of the topography of the Inferno."

Of the actual criticism the last chapter and the two appendices alone require special treatment, as they alone were written after the publication of "Amphimixis" and "The Germ-plasm."

It does not seem useful to insist with Dr. Romanes that the continuity of the germ-plasm is the inverse of the basis of the theory of pangenesis. The most important part of the continuity theory has no parallel in Darwin's provisional hypothesis. It is the attractive suggestion of a material basis of heredity which can be identified with structures visible under the microscope; which can be seen, in some cases, to separate immediately from the fertilised ovum to form the foundation of the germ-cells of the new individual, or, in other cases, to move along "germ-tracts" to the foundation of the germ-cells of the new individual. What is directly comparable in the two theories is the picture each gives of the phenomena of inheritance viewed in pangenesis as a rolling up of gemmules from an existing body to form germ-cells; in the germ-plasm as the unrolling of germ-plasm to form a developing body. In this, as Dr. Romanes points out, the one theory is the inverse of the other, and very naturally similar groups of facts may appear in the one as stages of rolling up, in the other as stages of disintegration. But here again Weismann, aided no doubt by the vast advance in microscopical science, constantly is more in touch with observed facts of microscopical detail than was Darwin.

Dr. Romanes uses a good deal of space for a minute and interesting comparison of Weismann's germ-plasm with the "stirp" of Galton. He urges that natural selection, so potent in the organic world, probably does not cease in the separate parts of a body during development, and therefore supports Galton's view of a competition among many gemmules of the same order as to which shall actually cause development. But natural selection is not a force: it is merely an aspect of certain occurrences, and while there may be many (as Galton thinks) or few (as Weismann thinks) units of germ-plasm each capable of causing development, and only one of which does cause development, the aspect of the occurrences on which Weismann wishes to direct attention is that the process of development goes on by an orderly disintegration of the germ-plasm through various stages of units, and that the order is determined by the "historic architecture" of the germ-plasm. This "historic architecture" is the material representation (on Weismann's theory) of the observed fact that ontogeny does to some extent repeat phylogeny. A continual struggle among innumerable units would account for too much variation, and would leave unrepresented the habitual fixedness of heredity.

In his criticism of Weismann's view of evolution Dr. Romanes first states how recent further investigations (those of Maupas and others) into the conjugation of Protozoa have led to an identification of conjugation with sexual reproduction, so far as they both result in a mingling of germ-plasm, but he quarrels with Weismann for not abandoning the potential immortality of the Protozoa. But whether Protozoa conjugate or not, on the broad average they divide by fission. That means that Protozoa alive to-day have come down in a continuous chain of cell-life from primeval Protozoa, unless indeed there have been continual re-creations of Protozoa. Even if it were proved that spore-formation invariably interrupted at long or short intervals chains of simple fission, still practical immortality may be held by regarding spore-formation as merely multiple fission.

In a more important criticism Dr. Romanes seems to me to misinterpret Weismann's position. When the continuity of germ-plasm first presented itself to Weismann's mind, and brought with it the idea that the somas of each generation were mere pendants of the chain of germ-plasm, it became difficult to see how the impression of outside nature on the soma could be impressed in turn on the germ-plasm. This led to an examination of a new kind into acquired characters, and the result of that examination satisfied Weismann and many others that there was no sufficient reason for supposing that characters acquired by the individual were transmitted to the progeny. Of course this is still a matter of argument, and as Dr. Romanes in this book refers to a full treatment of the question, the publication of which has been delayed by his regrettable illness, it may well be that he will adduce fresh and important considerations. But the fact remains that Weismann, driven back from acquired characters as a cause of phylogenetic variation, came to regard the mingling of germ-characters in amphimixis (traceable back to the direct influence of the environment upon organisms antecedent to amphimixis) as the source of all variation. The germ-plasm lived as a parasite within the soma, and was related to it only by the fact that it got food from the soma. In the more developed doctrine

Weismann retains the original conception. But the germ-plasm is now a particulate substance, and *inequalities of nutrition affecting the separate elements cause variations in it.* The original conception has now become more definite, and this increase in definition has effected a reconciliation with some strong objections to the generalised idea. It seems to me extraordinary that a critic so acute as Dr. Romanes, not in the heat of controversy but in a deliberate book, should call this "removing stone by stone, his doctrine of descent," and "turning upside down the fundamental postulate." In order to reach such a view he has had to be much more certain than Weismann, about what Weismann meant, and to attribute to "mere carelessness" the inclusion in Weismann's earlier writings of indications pointing in this direction.

In Appendix I. the germ-plasm is discussed specially in so far as Weismann considers pangenesis a less conceivable and a more formal explanation. I think the key to the criticism is again to be found in a misconception by Dr. Romanes. He quotes from Weismann:—

"How can such a process (*i.e.* the passage of gemmules into growing germ-cells) be conceivable when the colony becomes more complex, when the number of somatic cells becomes so large that they surround the reproductive cells with many layers, and when, at the same time, by an increasing division of labour, a great number of different tissues and cells are produced, all of which must originate *de novo* from a single reproductive cell?"

He goes on:—

"Here again the obvious answer is that no one has ever propounded such a statement. Far from supposing that 'all the different cells and tissues of a complex organism must originate *de novo* from a *single* reproductive cell,' the theory of pangenesis supposes the very contrary—viz. that somatic changes in the past history of the phyla had *not* thus originated in *any* reproductive cell. The idea of somatic changes originating in reproductive cells belongs to the theory of *germ-plasm;* but even this theory does not suppose all the great number of different cells and tissues which compose a complex organism to have ever originated *de novo* from a *single* reproductive cell."

What Weismann means seems clear enough, although it is dark to Dr. Romanes. The whole of a complex organism grows out from an ovum, and this origin occurs *de novo* in each generation. Pangenesis supposes that gemmules from each cell in the body somehow come together to form the ovum, and they come together so that they unroll in proper order. For this process there is no trace or shadow of evidence: to many it seems *à priori* inconceivable.

According to Weismann's theory the germ-plasm has been slowly built up in phylogeny, and slowly unrolls in the individual development. On any supposition the process is wonderful: on Weismann's hypothesis the evolution of germ-plasm has actually followed the evolution of living things from simple to complex, and there is no new wonder in its complexity, nor is the unrolling of the historically elaborated germ-plasm more wonderful than the actual development of the historically elaborated soma. The hypothesis of pangenesis supposes that in each living organism there is a new wonder, the giving off of gemmules, and their building up into an ovum which reproduces not only the structures which gave off gemmules, but many an embryonic structure dating far back in phylogenetic history.

Appendix II. deals with Telegony, and practically consists of Dr. Romanes' recent controversy with Herbert Spencer. In the mass of confused data about this subject it seems fairly established that at least it is very rare. The influence of a first sire does not as a rule affect children to a second sire. Herbert Spencer thinks that the established cases are fatal to Weismann's theory, inasmuch as they prove that influences impressed on the soma can be transferred to the offspring. Romanes thinks that they are not fatal, inasmuch as germ-plasm from spermatozoa of the first sire coming in contact with the ovary when a spermatozoon caused impregnation, might, as they disintegrate, allow some of their germ-plasm to penetrate the ovary and reach other ova. The actual explanation seems, to the present writer, a much simpler one, but as he is collecting facts he will only mention it. In the best established cases, as for instance Lord Morton's mare, and the sow quoted by Mr. Spencer, the first sire was of a more ancestral type than the second sire, and the characters in the progeny attributed to the influence of the first sire were atavistic, and in ordinary cases would have been simply referred to as throw-backs. But as at present Dr. Romanes' criticism of Weismann is the matter in hand, it is enough simply to point out that in this most difficult case for followers of Weismann, Saul also is among the prophets—Dr. Romanes agrees with Weismann! P. C. M.

EXTRA-TROPICAL ORCHIDS.

Icones Orchidearum Austro-Africanarum Extra-tropicarum; or Figures, with Descriptions of extra-tropical South African Orchids. By Harry Bolus, F.L.S. Vol. i. Part 1. (London: William Wesley and Son.)

THIS is an excellent work, devoted to the orchids of extra-tropical South Africa, and arranged on the lines of the "Refugium Botanicum" of Mr. Wilson Saunders. The first part includes fifty plates, containing figures and dissections (partly coloured) of fifty-one species. The text comprises descriptions in Latin and English, references to original descriptions, synonymy, geographical distribution, with critical and explanatory notes. The author's many years of careful study of South African orchids, as well as his previous writings on the subject, are sufficient guarantee of the quality of the work; and as regards the plates, a decided improvement is noticeable, both in the drawings and lithography, as compared with his previous "Orchids of the Cape Peninsula" (reviewed in NATURE, vol. xxxix. p. 222). The work will be of great use to the systematic botanist, for, as Mr. Bolus has well pointed out, few orders of plants stand more in need of illustration from living specimens than orchids, because of the high degree of specialisation of many of the parts, some of which are very fleshy, and seldom recover their shape after soaking or boiling. Nine new species are described in the present part, *Angræcum caffrum*, *A. Maudæ*, *Habenaria Galpini*, *Satyrium Guthriei*, *S. ocellatum*, *Pachites Bodkini*, *Disa sabulosa*, *D. conferta*, and *Brown*

leea Galpini. There are strong grounds, however, for suspecting that *Satyrium Guthriei* is not a true species, but a natural hybrid. It was described from a single living specimen found growing with *S. candidum*, Lindl., in burnt-off places on the Cape Flats, Tokai, near Cape Town, by Mr. F. Guthrie. Mr. Bolus remarks that the column "resembles in some degree that of *Satyrium bicallosum*, Thunb., while both are in this respect very different from that of any other Satyrium known. In every other character this differs greatly from *S. bicallosum*, and I very much doubt if it is a natural hybrid." This remark shows that Mr. Bolus had suspicions about the matter. It is a remarkable fact, however, that in every character in which *S. Guthriei* differs from *S. bicallosum* it approaches *S. candidum*; in fact, with the exception of the column, it bears a much closer resemblance to the last-named species, and as the organs generally are intermediate in character between those of the two species, there seems little doubt that it is a natural hybrid between them. Many such organisms are now known, and as both the species grow in the district, there is nothing improbable about the matter.

There are several points of interest about the work, one or two of which may be mentioned here. The discovery of a new species of Pachites is very interesting, as the original one has only been met with on four occasions. Burchell found a single specimen in 1815; Krausse met with another twenty-four years later; and now, after a lapse of fifty years, Mr. Schlechter has discovered two more specimens. Mr. Bolus hopes to publish a figure in the next part of his work. It is a curious coincidence that the new species is only known from a single specimen. An interesting note is given as to the affinities of Schizochilus. Sonder had indicated it as a member of the Habenarieæ, but Bentham transferred it to Diseæ. Mr. Bolus again places it near to Habenaria, and his drawings unmistakably show that this is its real position. Mr. Bolus calls attention to a very curious character found in *Satyrium pumilum*, Thunb., which Lindley referred to a separate genus. The flowers are transversely striped with brown, like a Stapelia, and to make the resemblance more complete, they also have a heavy odour of putrid flesh. As it differs so markedly from its allies in these characters, it is evident that we have here an adaptation to secure the visits of the insects which fertilise the Stapelias of the same region. And this reminds us that scarcely anything is known of the fertilisation of South African orchids. Mr. Bolus figures a beetle on the plate of *Disa elegans* (t. 35), which he found upon one of its flowers, with a pollinium attached to its thorax. It is said to be a species of Peritrichia, belonging to a group of well-known fertilisers. "This being only the second instance," remarks the author, "of an insect actually carrying orchid pollen which I have seen during many years' study of Cape orchids, I have thought it desirable to figure it with the plant." Among the undoubtedly handsome species may be noted *Disa ferruginea*, Swartz, and *D. graminifolia*, Ker. The former is noted as "abundant on Table Mountain," and its dark orange-vermilion flowers are "largely sold in bouquets in the streets." The latter was called *Herschelia graminifolia* by Lindley, though Mr. Bolus considers Herschelia as only a section of Disa. We are told that "it is one of the commonest species within our limits, has a rather long flowering period, and attracts universal observation by its beauty and brilliancy; so much so, that Lindley, in dedicating it to the great astronomer Herschel (who also was a great orchid-lover and cultivator), felicitously speaks of it as "species hæc pulcherrima *colore cœli australis* intense cæruleo superbiens!" Future parts of this useful work will be awaited with interest.

R. A. ROLFE.

OUR BOOK SHELF.

An Astronomical Glossary. By J. E. Gore. (London: Crosby Lockwood and Son, 1893.)

FIFTY years ago it was the fashion to insert a glossary or dictionary of astronomical terms in every work on astronomy, but few of the books published in late years include these helpful explanations. Mr. Gore endeavours to supply the need in the volume before us. And if the science of astronomy had made no advances during the last half-century, we should have been able to give the highest commendation to his compilation. But since celestial science has had its limits considerably extended, and the old astronomy is giving place to the new, we naturally expect to find the new terms defined in a glossary which pretends to contain "an explanation of all the terms and names generally used in books on astronomy." We were greatly surprised therefore, upon looking through the book, to notice the omission of many common and important words to be found in almost every work on astronomy. Among other omissions are the words corona, prominences, chromosphere, photosphere, spectroscope, and prism. Zones are correctly described, and are exemplified by "torrid zone," "frigid zone," and "temperate zone," but the term "sun-spot zone" is unexplained. No mention is made of spectroscopic binaries, or of motion in the line of sight, or of zodiacal constellations. Stereograms are defined, but not spectrograms—that useful word coined for spectroscopic negatives. Neither meridian instrument, nor meridian circle are indexed. In fact, so many words constantly employed in astronomy at the present time are omitted, that we have come to the conclusion that Mr. Gore has only attempted to include in his glossary words used when he was a schoolboy. The tables of data merely refer to members of the solar system, and their value would be increased if the solar parallax were given which formed the basis of their computation. Lists of remarkable red stars, variable stars, and stars for which orbits have been computed, conclude the book—a book that might have been very handy to latter-day astronomers, but which in its present form is of no use whatever.

With the Woodlanders and By the Tide. By "A Son of the Marshes." Edited by J. A. Owen. (Edinburgh and London: William Blackwood and Sons, 1893.)

THE author of this book is well known as a close observer of nature; and a more enthusiastic lover of natural creatures and things for their own sake it would be difficult to find. To look at flocks of bramble finches feed in some particular old beech-woods at sunrise, he trudged for five miles through snow-covered woodlands; and the book is filled with accounts of similar sights observed at all times of the day and seasons of the year. In fact, "A Son of the Marshes" is imbued with the true spirit of a naturalist—the spirit that leads men to sacrifice everything in order to obtain a clearer insight into nature.

An interesting instance of protective colouration is given on p. 163. Some broken egg-shells of the fern-owl having caught the author's eye, he looked closer into the fragments, and saw what appeared to be a short, crooked

bit of dead furze stem. As he was bending over it, the supposed withered stem moved slightly, and gave him the impression that he was looking at the back of a large viper that had half buried itself in the furze. A still closer scrutiny showed that the semblance of a crooked piece of furze was two fern-owls about three days old.

We have read the book from cover to cover, and have been interested throughout. The author has looked to animate nature for his facts; hence his work possesses the sterling ring which every student of science delights to hear.

Pitt Press Euclid, V.-VI. By H. M. Taylor, M.A. (Cambridge: Univ. Press, 1893.)

We have previously had occasion to refer to the earlier issues of this series of books on the elements of Euclidian geometry. The present publication is quite up to the standard of the former ones, and contains some important variations from the usual mode of treatment. In dealing with the fifth Book, Mr. Taylor rejects altogether the use of figures, since, as he rightly says, the book is not essentially geometrical. With a general knowledge of proportion as derived from treatises on algebra, a student is sufficiently equipped to follow its applications in Book vi. The numbering of the propositions is somewhat altered owing to the omission of some of the propositions in the Greek text. With regard to Book vi. Mr. Taylor has made some modifications in the treatment of similar figures, and many theorems are more briefly proved by adopting the definition of similar polygons there enumerated. The additional theorems which are inserted have been arranged in series—one, for instance, giving the student a sketch of the theory of transversals, harmonic and anharmonic ranges and pencils, leading up to Pascal's theorem; another of nine propositions, concluding with Gergonne's neat solution of the problem to describe a circle to touch three given circles. The method of inversion, Casey's extension of Ptolemy's theorem, properties of coaxial circles, and some porismatic problems follow next in order, the book concluding with a capital set of exercises and an index for the first six books.

The Out-door World, or Young Collector's Handbook. By W. Furneaux, F.R.G.S. (London: Longmans, 1893.)

A great deal of information useful to the young collector, for whom Mr. Furneaux has prepared this handbook, is to be found in its four hundred pages. There are sixteen coloured plates, some of which are excellent and none bad, and more than five hundred illustrations in the text. Those of birds are somewhat unequal; some indication of relative size would have been helpful. The linnet and the cuckoo are placed side by side, and the former is apparently the larger of the two, while on the opposite page the great tit is considerably bigger than the lark, and rivals the cuckoo in apparent proportions. If the length of the bird had been given in brackets after the name under each figure, it would have prevented misapprehension. We have dipped here and there into the letterpress, and found the information accurate and clearly put.

Worked Examples in Co-ordinate Geometry. (Univ. Corr. Coll. Tutorial Series.) By William Briggs and G. H. Bryan. (London: W. B. Clive and Co., 1893.)

The examples which are here brought together are intended to serve as a graduated course on the right line and circle, forming thus a useful companion to the book on Co-ordinate Geometry already published by the same authors. The work line is specially designed for the private student, and this is why the problems have been dealt with in such detail, every step in their solution being clearly explained. The examination papers may fairly be taken as good test papers, for the questions seem to have been carefully selected, and the more important ones on book work are not lacking. For those teaching themselves this subject by working out the problems given, a good insight should be obtained, while the references to the author's work on co-ordinate geometry, above referred to, will be found very useful to those possessing that book.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Sir Henry H. Howorth on "Geology in Nubibus."

Having given my views on glacial geology in the current issue of the *Fortnightly Review*, to be followed by one dealing at some length with the ice-origin of lake-basins, I should not have thought any reply to Sir Henry Howorth's "Appeal" necessary except for the consideration that my articles may not be seen by many readers of Nature. And first, I would remark, that the mental attitude which Sir H. Howorth imputes to extreme glacialists I have myself been unable to detect in their writings. In fact, I was under the impression that the "scoffing" and "jeering" was chiefly from the other side; but it seems I was mistaken, and I must apologise for my ignorance. Those who read my articles will see that I make no appeal to "transcendental ice," but judge of its powers and properties by its admitted effects. Sir H. Howorth says that "ice is known to crush under moderate pressure," implying that a glacier a mile or perhaps half a mile thick is impossible. But will he or anyone else tell us what happens to the ice after it is crushed, and the pressure that crushed it is continued and slowly increased? Will it not suffer re-gelation and become denser ice; and if by sudden increase of pressure it is again crushed, will it not by still further pressure again suffer re-gelation? He stops at the first "crushing," as if that were the end of all things so far as a glacier is concerned. All this, however, is beside the question from my point of view. The work of ice on the rocks is as clear as that of palæolithic man on the flints; all the difficulties that may be suggested as to how he lived, or how he shaped the flints do not in the slightest degree affect our conclusion that the palæolithic flint implements are the work of *man*; and there is equally clear evidence that ice *did* march a hundred miles, mostly uphill, from the head of Lake Geneva to Soleure, whatever transcendental qualities it must have possessed to do so.

As to "perhaps the largest and most remarkable collection of rock-basins in the world"—the largest being of 50 acres and the deepest 30 feet deep—I must really decline to occupy your space in showing how simply these may have been produced by ordinary denuding agencies, or in denying that any glacialist, even of "the most extreme and aggressive school," would claim them as proofs of glaciation. As regards the question of Tasmanian glaciation, my last communication to Nature (Nov. 2) seems to me to render any further observations unnecessary. No doubt the conclusions of the various writers will be fully harmonised by a more complete study of the whole region.

The last point touched on by Sir H. Howorth—whether the advocates of the ice-origin of certain groups of lakes are "extravagant" in their views, following the methods of Aristotle rather than those of Bacon, and founding their beliefs on "purely hypothetical properties of matter and forces of nature"—I will leave to the judgment of those who do me the honour of reading my forthcoming article in the *Fortnightly Review*.

Alfred R. Wallace.

The Erosion of Rock-Basins.

Mr. T. D. LaTouche's letter (page 39) is very interesting as a more than usually independent contribution (for the reason given therein) to the interesting question of glacial

erosion, and as showing how similar (allowing for the difference in size) are the phenomena of the Himalayan and the Alpine glaciers. But I think that moulins, as a rule, are not likely to be very important agents in the formation of the rock-basins in which lakelets and tarns are often lodged. So far as my experience goes, the range over which the moulin-torrents can act is very restricted; for the crevasse, which gives the opportunity to the water, is generally formed very nearly at the same part of the glacier. Thus after the moulin has travelled for a very short distance down the glacier, a new crevasse opens out behind it and cuts off the torrent. I have frequently seen four or five dry shafts in advance of the working moulin. The lateral range also of the moulin must be small. Hence I think that the giant's-kettle (as is usually supposed) more accurately represents the ordinary product of a moulin. An excellent illustration is afforded by the well-known "glacier-garden" at Lucerne. I think, also, that the rock-basins, of which we speak, are more commonly found in situations where moulins would not be numerous or large, viz. in cwms and corries. It is, however, true that in certain undulating rock districts, as parts of Scandinavia and the Scotch Highlands, lakelets are common. The form of these, however, does not appear to bear much relation to the hollow produced by a moulin. So that I doubt whether we can regard a moulin as an agent of primary importance in the production of an ordinary rock-basin, though it may sometimes be a minor contributory. As I have more than once discussed the question of the probable cause of the formation of tarns as well as of large lake-basins, it is needless to repeat what has appeared in print.

T. G. BONNEY.

23 Denning Road, N.W., November 13.

"The Zoological Record."

IN your Notes for October 26, on p. 621, you follow the Editor of the *Zoological Record* in suggesting that, under the present financial conditions, palæontology should be removed from the volume issued by the Zoological Society, and provided for by the palæontologists themselves. Against such retrogression we desire to protest. "Everyone knows," as you say, "that an incomplete record is of very little use"; and how absurdly incomplete a record would be that took no account of palæontology! The objectors probably spring mostly from the ranks of systematic zoologists. We will deal with them on their own ground. The systematic position of *Limulus* has long been a vexed question, which no one can attempt to solve without consulting the work of Malcolm Laurie on the fossil Eurypterids. The classification of the Crinoids has troubled zoologists since the days of Johannes Müller; but neither he nor anyone ever dreamed of settling it without reference to palæontology. Students of recent Bryozoa will not be grateful to those who keep them in ignorance of J. W. Gregory's lately published work on the Bryozoa of the early Tertiary rocks. And so we might go on *ad infinitum*. Another argument that may affect the systematists is that if they reject all names of fossil genera and species from the record, they will have no means of knowing whether the new names they may wish to propose have been used before or not. It is even possible that some of them may unwittingly describe as new forms already described by some unknown palæontologist. It is hardly necessary to remind the morphologists, embryologists, and zoögeographers of the help that they constantly receive from the palæontologists; they, at least, will not wish to have the record made incomplete.

It is suggested that every branch of science should have a record, and that palæontologists should undertake the compilation of a separate one. This would as good as double the work, both for recorders and students. What we have said above shows that palæontology is not a separate science. Zoologists and palæontologists ought to be the same people, and when they have strength enough they are so, as the names of Cuvier, Owen, and Huxley sufficiently testify. The palæontological recorder would still have to work through the writings of the zoologists, while even the pure neontologists would have perpetually to refer to the palæontological record.

What is really wanted is to complete the *Zoological Record*, not to make it incomplete—to go forward, not backward. It is admitted that some of the recorders do tackle the palæontological literature. Why should not all? If a group is too large for one man, then give it to two, and if a second man cannot be got to work on half-pay, then double the pay.

To prevent the record becoming too big, make it merely an index, and cut out the abstracts, which are rarely correct. If more money is wanted, appeal to other societies which might naturally be supposed interested in the work. It is unfair that a single society should bear the burden of a work that is of value to all, and one can hardly suppose that it would refuse kindly offers of help. We believe, indeed, that the only reason why some of the recorders abstain for the present from the palæontological work is because they feel that part, at least, of the expense ought to be borne by the society more directly interested.

British Museum (Nat. Hist.), October 30.

Recognition Marks.

A QUESTION in natural history has occurred to me, which, I think, might with advantage be discussed in your columns.

It is usual to account for the white tail of the rabbit (*Lepus cuniculus*) by saying that it is useful as a danger signal to others of the species. Wallace, in his "Darwinism," speaking of rabbits, says that "the white upturned tails of those in front serve as guides and signals to those more remote from home."

Now, there appear to me to be two objections to this theory. The first is that the tail of the hare (*Lepus timidus*) is also white, and is turned up in precisely the same manner when running; but it is obvious, from the habits of this animal, that in its case it would be quite unnecessaary for such a purpose.

And in the second place, if this were so, how could it have been produced by evolution? The object of the white tail is said to be to assist other rabbits to escape, not the possessor of the white tail itself. But the principle of evolution is the survival of the animal fittest to preserve its own life, not of the fittest to preserve the lives of others of the same species.

G. J. MACGILLIVRAY.

3 Belford Park, Edinburgh, November 6.

MR. MACGILLIVRAY has failed to grasp the principle of natural selection when he thinks that it cannot produce a character useful to other animals of the same species. The action of natural selection is to preserve the *species*, as well as each individual separately; and, consequently, every character useful to the species as a whole would be preserved. This is obvious when we consider such characters as nest-building in birds, and milk-secretion in mammals, which do not benefit the individual possessors, but their offspring; and the same principle applies to every character which is mutually useful to individuals of the same species, as are what I have termed "recognition characters." Neither can I admit that the habits of the hare render the white upturned tail "quite unnecessary." The hare is a nocturnal feeder, and a mark which readily distinguishes a friend from an enemy, and enables the young during their short period of infancy to keep within sight of the mother, must be of considerable importance.

ALFRED R. WALLACE.

Correlation of Solar and Magnetic Phenomena.

IN writing on this subject (NATURE, vol. xlix. p. 30), to save space I omitted to refer to one other case of presumed connection. But as such omission might be misunderstood, may I here briefly allude to it? M. Trouvelot, on June 17, 1891, observed changes going on in connection with a luminous appearance near the western limb of the sun, such as he had not before seen. But the magnetic movement was in this case insignificant (see *The Observatory*, vol. xiv. pp. 326-328). The same reasoning as before may be applied. If the smaller magnetic motions do really directly depend on solar changes of so marked a character, how does it happen that many greater recorded magnetic movements remain without corresponding solar change having been seen? It is a very interesting, indeed critical point, but much more information is necessary to prove that such close connection really exists.

The appearance was seen by Trouvelot near the sun's limb. There is a significant sentence ending a letter from the Rev. Walter Sidgreaves, of Stonyhurst (*The Observatory*, vol. xiv. page 326), as follows:—"But there are no indications of magnetic disturbance accompanying the solar eruptions seen through the spectroscope. Even the brilliant display on the western limb, of the 10th [September 10, 1891], has left nothing that

can be considered a record of itself on the magnetograph curves." William Ellis.

Greenwich, November 9.

[With regard to the case cited by Mr. Ellis, it is worth remark that at the time of Trouvelot's observation, the writer of our "Astronomical Notes" asked Mr. Whipple whether the eruption was accompanied by any anomalous magnetic movements. Mr. Whipple replied: "There was not the slightest magnetic disturbance on June 17, 1891, at the hour you mention, or for days before or since." The point was again raised at the beginning of last year, and to make assurance doubly sure, Mr. Whipple again referred to the Kew curves, but failed to find any trace of what could be termed a magnetic disturbance at the hour in question. (See Nature, February 25, 1892.)—Ed.]

THE NEW BIRD-PROTECTION BILL.

SENTIMENT is a beautiful thing in its way, and when that way happens to coincide with the way of common sense, the man must be a brute who defies it. But unluckily that does not always happen, as is testified by several instances that could but here shall not be cited, for they will come uncalled to the recollection of many of our readers, and indeed to some they are ever present. These need not to have the difference between a sound and an unsound sentiment pointed out. But there is also a sentiment that is perfectly sound at the start, and yet, chiefly through want of knowledge—we hesitate to call it ignorance, because that might imply blame—sooner or later begins to betray symptoms of running on the wrong track, when, if the brakes cannot be applied, it comes into violent collision with common sense. As the latter is the weightier mass the harm it gets from the impact is not often very serious, and the injuries received seldom cause more than delay, however annoying that may be; but the effect on the lighter body is apt to be destructive, and though in some cases it may be only repelled with slight damage, in others it may be shattered. In either event, seeing that it set out with good intentions, the result is to be regretted.

Of this kind of sentiment is that which actuates the extreme advocates of Bird Protection. Time was when the sickening slaughter of sea-fowl at their breeding-stations around our coast appealed alike to sentiment and to common sense—to say nothing of science—to interfere. First carried on for what was called "sport," but soon for the sake of mere lucre, the feathered denizens of our cliffs and beaches were shot down by the thousand, to do nobody any good but the "plume-trader." The Act of Parliament which received the Royal Assent in June 1869, and is always to be remembered in connection with the name of Mr. Christopher Sykes, was just in time to save from extinction the population of many a thronged resort which has always presented, and we trust always will present, a spectacle of delight to the large and increasing class of our fellow-countrymen who appreciate the harmonies of nature, even if the resorts on the English coast cannot compare with those

> ——where the Northern Ocean in vast whirls
> Boils round the naked melancholy isles
> Of sea-girt Thule, or the Atlantic surge
> Pours in among the stormy Hebrides.

That Act may have had its shortcomings: few Acts are without them; but nobody can doubt it was effective to do good, and it was followed by other Acts, based on the same principle, and tending to relieve persecuted beings from persecution. An exception indeed must be made as regards one of them, but that one (which was commented upon at the time in these columns [1]) only serves to support the allegation in our introductory paragraph. In 1872 some enthusiasts followed the line of sentiment regardless of common sense, and succeeded in converting a well-considered and practical measure into one that was specious and useless. They had their reward, for in the next session their parliamentary leader obtained a Select Committee of the House of Commons to enquire into the subject, and the result of the investigation showed every reasonable person the baselessness of the points for which the extreme party had contended, while three years later the very Bill which they had mutilated and mauled passed through Parliament almost exactly in the form in which it had been originally introduced. The enthusiasts, however, had the satisfaction of stopping useful and much wanted legislation for four years in order to gratify their own gushing and unintelligent sentiment, while their Act, always a dead letter, was superseded by the Act of 1880 which consolidated all previous legislation. Still the spirit that moved the enthusiasts is not dead. In one way or another it shows itself every year—sometimes, though not often, it confines itself within the bounds of common sense, but of late it has become we may say rampant. None of the former Acts had done anything to stay the taking of birds' eggs. Indeed, birds' eggs had been, and that purposely, wholly left out of consideration, and this in the eyes of many excellent people has seemed to be a glaring defect—even a crime. Let us stop birdsnesting, say they, and the number of our birds will be indefinitely increased. Nightingales will multiply, Goldfinches will be as plentiful as Sparrows, and Skylarks will swarm. Little do these good people realise the state of things. Let us grant that in the immediate neighbourhood of towns and large villages, where birds are already at a disadvantage, boys will emerge, and successively rob nest after nest as it is built with an effect that may be called devastating. The case, however, is very different in the country at large. There the first species of those we have just named already enjoys a protection incidentally yet almost invariably conferred upon it by the law of trespass. We can believe almost any act of folly or stupidity on the part of some game-keepers, and the widely-told story that one of that profession once declared that he destroyed Nightingales because their singing disturbed the nights' rest of his pheasants may have some foundation; but nearly all observers who have informed themselves by experience will agree that the part of England which Nightingales choose to occupy is generally as fully stocked with them as the place will hold. It is certain to those who watch that the number of Nightingales which return to this country with each returning spring is greater than that which can find room. Hence those ever-recurring contests of melody that we hear from rival cock birds on their first coming, to say nothing of the actual conflicts, often ending in the death of one of the combatants, that take place between the competitors. And it is only natural that it should be so. That if a Nightingale's nest be taken the same birds immediately build a second, and if need be a third, is a perfectly well-known fact, and it would be a very unlucky pair of Nightingales to have their nest robbed thrice in a season. At a very moderate computation the number of young Nightingales that must annually attain their full growth in this country doubles that of their parents, since from five to six are commonly reared in each nest; and, with a large allowance for casualties in youth, it is safe to calculate upon four of each brood having reached maturity when the time of emigration arrives. What happens during their absence from this country is of course beyond our ken, but the certainty with which migratory birds return to their home is now well-recognised; and it is not less certain that of this species more return to England in spring than are able to find accommodation in our woods, coppices, and shrubberies, as the conflicts just mentioned testify. Hence it would follow that were the taking of a Nightingale's egg made a capital offence, we should not have, one year with another, more Nightingales, though, to retain the number we have, it is impera-

[1] Nature, viii., p. 1, (May 1, 1873).

tive that the old birds should have protection at the breeding season.

To take the second case we have cited, that of the Goldfinch, the details are not the same, though the final result be so. Until some fifteen or twenty years ago the diminution in the numbers of this species was notorious; but the reasons of that diminution are easily revealed to any enquirer, though it may be hard to say which of them be the stronger. The practice of netting in spring time, now illegal though probably still used in some places, was carried on to an extent that if it were not supported by the clearest evidence people would hardly believe. Combined with this disastrous practice was the fact that so much heath and common land had been brought under the plough, and the mode of agriculture so much improved, as sensibly to affect the Goldfinch's supply of food, for its fare was truthfully termed by the poet "the thistle's downy seed," combined however with that of other weeds hated by good farmers. But no doubt, at the hands of the bird-catchers, the Goldfinch, being so great a favourite for the cage, still suffers severely, and it may be true that enough do not leave this country at close of summer to satisfy the waste of life that occurs during its migration and in its winter-quarters; though as to any considerable diminution in its numbers being caused by birdsnesting, the notion of such a thing will be scouted by all who have had opportunities of observing its breeding-habits. Our third instance, the Skylark, is without doubt one of those birds that needs protection least. Nobody persecutes him so soon as he ceases to flock and settles with his mate in their chosen spot. Their nest in the growing corn, or the wide pasture, is safe from even the predatory rat, and the open country they haunt is no place for the Sparrow-hawk, that deadly foe to so many small birds. There, in the course of the season, they make their three or four nests, and rear in each as many young, so that the annual increase of the species may be safely computed as five-fold, and when we also consider that thousands if not tens of thousands arrive every autumn on our shores and spread over the whole country, with a safe conscience the most devoted lover of birds may, if he has a mind to it, eat lark-pudding in winter without compunction.

We have cited these three cases—the Skylark, the Goldfinch, and the Nightingale, because we have them so frequently put forward by sentimentalists as birds that all right-minded people would wish to see more numerous. We should like to count ourselves among the right-minded, but the sentimentalists must forgive us for refusing to believe that the number can be increased in the way they advocate—visiting with punishment the schoolboys who would take the nests of any one of them. Far otherwise, however, is it with many birds of which the enthusiasts never think. Those, for instance, that habitually breed in places open to all comers, and especially on islands near our coast, on the sea shore, and by the side of inland but navigable waters. In such places there is no law of trespass; and, as all who have been at the pains to inform themselves know, these birds suffer from the way their exposed nests are ravaged, and are surely decreasing in number. Yet by the general public they are little heeded, chiefly because the general public knows nothing about them—not even their names—and moreover encourages the ravages by blindly buying the booty of the ravagers. Thus it is that many a beach, and many a heath, and many a marsh and mere, is made desolate, for the ravage is continued throughout the whole of the breeding-season, with the result that scarcely an egg is left from which a young bird—be it Duck or Gull, Tern or Plover can be hatched. Yet it is obvious that it would not be so very difficult to stop this destruction, and that without interfering with the long-established practice, which we hold to be no more detrimental to their species than it is illegitimate, of taking toll of their eggs. Pick out the places at which the practice is carried on, and limit the time during which the eggs may there be lawfully gathered, so as to give each pair of birds the opportunity of bringing off their brood.

Early in the present Session a "Bill to amend the Wild Birds' Protection Act, 1880," was brought into the House of Commons by Sir Herbert Maxwell, which Bill, owing to the well-deserved popularity of its introducer, ran its course unchallenged, and achieved the almost unexampled success of being read a third time and passed with scarcely an alteration of importance. The scope of the Bill was to enable any County Council to prohibit "the taking or destroying of any species of wild bird or the eggs of any species of wild bird." This Bill, of course, attracted the attention of the Committee which had been appointed the year before by the British Association "to consider proposals for the Legislative Protection of Wild Birds' Eggs," and in the opinion of that Committee, as subsequently reported at the late meeting of the Association at Nottingham, the Bill was declared to have been framed on a mistaken principle "in that it sought to effect the desired object by empowering local authorities to name the species,[1] the eggs of which were to be protected, thus requiring in every case of prosecution proof of identity, which in the majority of cases would be difficult, if not impossible to supply."

The House of Lords at first took almost precisely the same view as the British Association Committee; and, chiefly at the instance of Lord Walsingham, than whom there could scarcely be a more competent peer, amended the Bill accordingly, producing what would, in the opinion of many experts, be a very workable measure. But unhappily in the subsequent process of passing the Standing Committee of the Upper House, their lordships were induced, by those who were not experts, to go a great deal further, and nobody acquainted with the facts of the questions involved, can doubt that on this occasion the efficacy of the Bill was not a little damaged in various ways. In this condition it in due course returned to the House of Commons, where the British Association Committee, as stated in their report, hoped it would, in spite of its transformation, still find favour; but its original parent, Sir Herbert Maxwell, would have none of it, and consideration of the Lords' Amendments having been adjourned on August 21 for three months, it stands by the accidental prolongation of the Session, for further discussion in a few days. In the meanwhile the British Association Committee has been reconstituted and strengthened by the substitution of several ornithologists of repute in place of some naturalists who had never paid any special attention to the matter, while Sir John Lubbock has accepted the post of chairman, and Mr. Dresser, who was for many years Secretary to the Old "Close-Time" Committee of the Association that effected so much good, undertakes the same duty in the new body, the other members of which are Mr. Cordeaux, Mr. W. H. Hudson, Prof. Newton, Mr. Howard Saunders, Mr. T. H. Thomas, Canon Tristram, and Dr. Vachell. With a chairman at once so conciliatory and so influential, and a secretary of so much experience, it may be hoped that the difficulties, great as they are—for they involve a contest between the two Houses of Parliament—will not prove insuperable, and that some way may be found of saving this Bill, for all will admit that if it be not passed this Session a long while may elapse ere a House of Commons is good-humoured enough to let a measure of the kind slip through its entanglements, as did that of Sir Herbert Maxwell at the beginning of this year. This is surely a case where sentiment should yield to common sense.

[1] It may be remarked that the Bill was so carelessly worded as to leave it open to doubt, though this was certainly not the intention of its supporters, whether a County Council could by one act make it apply to all Wild Birds, or only to some that should be named.

LIGHT-WAVES AND THEIR APPLICATION TO METROLOGY.

EVERY accurate measurement of a physical quantity depends ultimately upon a measurement of length or of angle: and it will readily be admitted that no effort should be spared to make it possible to attain the utmost limit of precision in these fundamental quantities. At present, lengths are measured by the microscope, and angles by the telescope; and the extraordinary degree of accuracy already attained by the use of these instruments depends entirely on the properties of their optical parts in their relation to light-waves; so that, in fact, light-waves are now the most convenient and universally employed means we possess for making accurate measurements. It can readily be shown that this high degree of accuracy is especially due to the extreme minuteness of these waves.

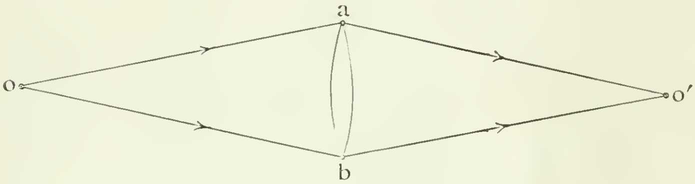

FIG. 1.

Thus it is well known that the image of a luminous point consists of a series of concentric coloured rings surrounding a bright central disc which is smaller the smaller the ratio of the wave-length of the light to the diameter of the objective employed. In fact, it can be shown that the radius of the bright central disc contains as many wave-lengths as the distance of the image from the objective contains the diameter of the objective. Thus in a telescope twenty diameters long, the diameter of the bright disc is forty wave-lengths or 0·02 mm. If the image be magnified by increasing its distance from the objective, or otherwise, these diffraction rings are magnified in the same proportion; so that nothing is gained thereby in *distinctness*, beyond the point where the rings are just large enough to be visible. But, were it not for the inevitable loss of light, it would be advantageous for *measurements of position* to increase the magnification much further.

This can be accomplished by an extremely useful instrument which has been misnamed the "interferential refractometer." It will be interesting to note that notwithstanding the apparent difference in form, this apparatus, when used as a measuring instrument, differs in no essential particular from the microscope or the telescope, or (what is perhaps a trifle unexpected) the spectroscope; and it is possible to change any one of these instruments into the other by unimportant modifications.

Thus, let *o*, Fig. 1, be a source of light, *a b* a lens which forms an image of *o* at *o′*. The operation of the lens, when used to distinguish minute objects, depends upon the accuracy with which all its parts contribute to make the elementary waves reach the focus in the same phase of vibration; but to determine the position of *o* with respect to *a b*, this is not at all necessary; and in fact, if we disregard the possible inconvenience due to the dissimilarity between the phenomenon observed and the object whose position is to be measured, it would be as well to entirely annul the central portions of the lens, leaving only an external annular ring, or better still, only two small portions at opposite ends of a diameter.

This involves no sacrifice of accuracy, but on the contrary a very considerable gain; for it is now possible to increase the size of the interference fringes up to any desired limit without diminishing the intensity of the light, the result being the same as could be obtained with a perfect microscope of unlimited magnifying power with a source of unlimited intensity.

For this purpose the two small portions to which the lens is reduced are replaced by plane mirrors or prisms, whose office is simply to bring the two interfering pencils into coincidence. Further, the pencils, instead of starting from a point or a line, may be separated by a plane transparent surface; and a second similar surface may be used to reunite the pencils after reflection. Thus the telescope or microscope will have been converted into a refractometer. The exact nature of the analogy will be apparent by a comparison of Figs. 1 and 2.

It may be assumed that under the most favourable circumstances the utmost attainable limit of accuracy of a setting of the cross-hair of a microscope on a fine ruled line is about $\frac{1}{20}$ of a micron. Now, it is usually admitted that the middle point of an interference fringe, if it be sufficiently broad and clear, can be determined within about $\frac{1}{50}$ of the width of a fringe. In the refractometer this would mean only $\frac{1}{100}$ of a light-wave, or about 0·01μ, from which it would follow that the refractometer is about five times as accurate as the microscope. But a number of trials with the form of refractometer shown in Fig. 8 gave as the mean error of a series of ten observations:

Morley Fr. 0·0056 ...	Nicholson Fr. 0·0059 ...	X Fr. 0·0110

The third observer had no previous practice in this kind of measurement.

It is evident from these results that $\frac{1}{50}$ of a fringe is too large an estimate of the average error of a setting, and that it is, in fact, less than 0·01 of a fringe, corresponding to an error in distance of about 0.003μ.

For angular measurements the microscope is replaced by the telescope.

Fig. 3 represents a disposition sometimes adopted for observing minute angular displacements of the mirror *d c*: the light starts from *o*, is reflected by the plane parallel glass plate *p* to the objective *a b* of a telescope, whence the now parallel rays proceed to the mirror *c d*. Thence they retrace their path to the plate *p*, through which they are transmitted, forming an image of the source at *o′*, which is viewed through the eyepiece.

Fig. 4 is the exact analogue in the form of a refractometer; and Fig. 5, though slightly different in aspect, is still essentially the same instrument. The path of the

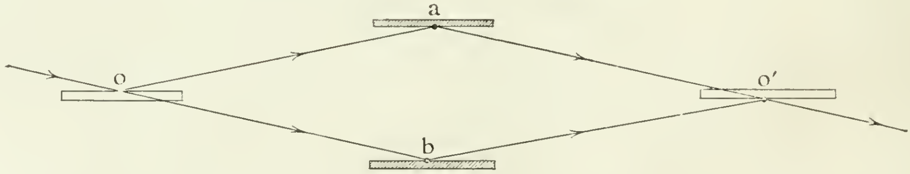

FIG. 2.

rays is *o p a c a p o′* for one of the pencils, and *o p b d b p o′* for the other.

From considerations quite analogous to those employed in the former case, it can be shown that the

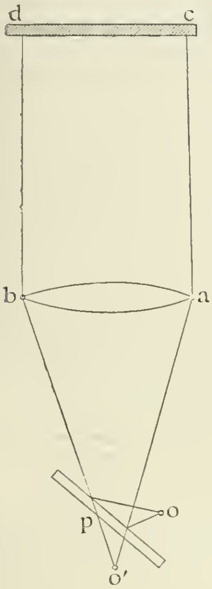

Fig. 3.

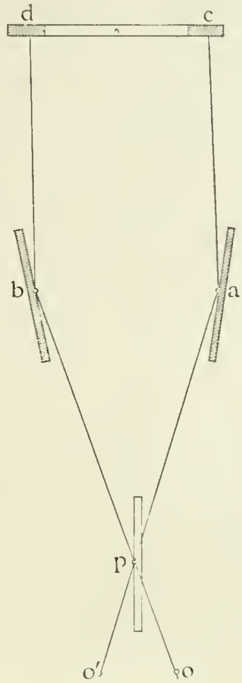

Fig. 4.

limit of accuracy attainable in the estimations of angles involves an error of about one-fifth of the angle subtended by a light wave at a distance equal to the diameter of the objective. This is halved by the fact that the angular motion of the beam is twice that of the mirror; so that

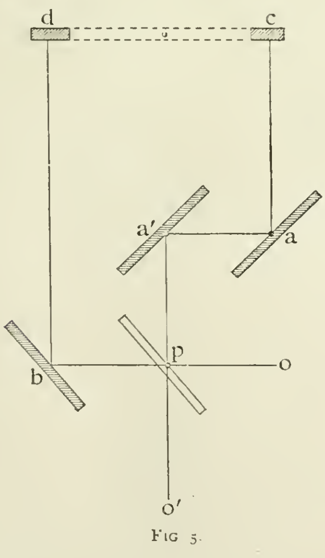

Fig 5.

with a telescope of 10 cm. aperture the limit of accuracy may be estimated at $\frac{1}{2000000}$, or say 0.1″. But taking 0.01 fr. as the smallest perceptible displacement of the mirrors *c d*, the corresponding angle of rotation of the line *c d* (10 cm. long) would be only $\frac{1}{20000000}$, or say 0.01″.[1]

It is not at first evident that there is any relation between the refractometer and the spectroscope. A comparison of Fig. 6 and Fig. 7 shows, however, that there is a strict analogy. Fig. 6 represents a disposition sometimes adopted to observe the spectrum by means of a concave grating, and Fig. 7, with unimportant modifications, is the arrangement actually employed in the analysis of radiations by means of their "visibility curves," as will be explained below.

Exactly as in the case of mirrors and lenses, we may here, too, sacrifice "resolution" and "definition" by using only the extreme portions of the surface, with an actual gain in "accuracy." To compare numbers, it appears that the average error in the comparison of

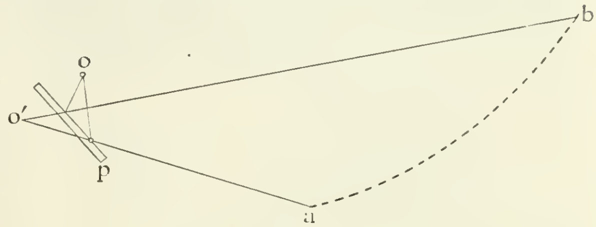

Fig. 6.

wave-lengths by a grating with 250,000 lines is about one part in half-a-million. With this number of waves in the difference of path of two interfering pencils, the corresponding error in the refractometer observations are of the order of one twenty-millionth.

The name "interferential refractometer" seems rather inappropriate to an instrument which has so many important applications beside the measurement of indices of refraction; but as it has been sanctioned by long usage it will be retained.

Among the many forms of the apparatus which have been rendered classic by the works of Arago, Fresnel, Fizeau, Jamin, and Mascart, and which are so admirably adapted to the work for which they were designed, there are none which are not open to serious objections when applied to the solution of such problems as the measure-

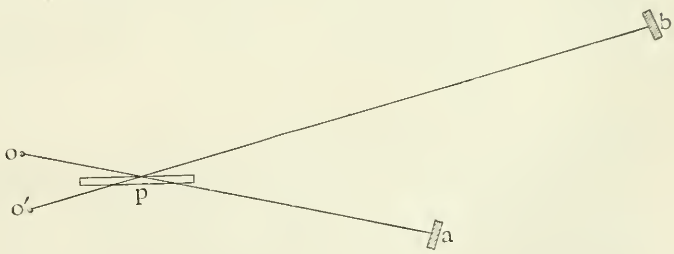

Fig. 7.

ment of lengths and angles, for the analysis of the constitution of the light of spectral lines, and especially for the determination of wave-lengths in absolute measure. For these, the form of instrument shown in Fig. 8 has many important advantages, among which the following may be mentioned:—It is simple in construction, and is easily adjusted; it may be used with a broad luminous

[1] In the use of the revolving mirror as in galvanometers, gravity and torsion balances, &c., the accuracy can be increased by enlarging the surface of the mirror; but the moment of inertia is thereby increased, and in greater proportion. But in the refractometer the mirrors *c d* may be made insignificantly small, and yet, with the same distance between the outer edges, the accuracy may be increased at least tenfold. It is important to note that any linear motion of the line joining the mirrors, or even a rotation about this line, has no effect on the fringes. It seems probable that this form of instrument may be of service in such problems as the measurement of the moon's attraction, constant of gravitation, variations of the vertical, &c.

surface as source of light; the pencils may be separated as far as desired; its range of difference of path between the interfering pencils is unlimited; and when properly adjusted the position of the interference fringes is perfectly definite, so that there is no uncertainty on account of parallax, and no difficulty in counting the number of fringes passing a given point. Finally, it may be added, that this is probably the only form of instrument which permits the use of white light (and consequently of the identification of the fringes) in the determination of the position or inclination of a surface without risk of disturbance due to contact or close approximation.

As shown in Fig. 8, the refractometer consists essentially of a plane parallel plate of optical glass G_1 and two plane mirrors M_1 M_2. The beam of light to be examined falls on the plate G_1 at an angle, usually 45°, part being reflected and part transmitted.[1] The reflected portion is returned by the mirror M_2, and passes back through the inclined plate. The transmitted portion is returned by the mirror M_1, and is reflected by the inclined plate, and from

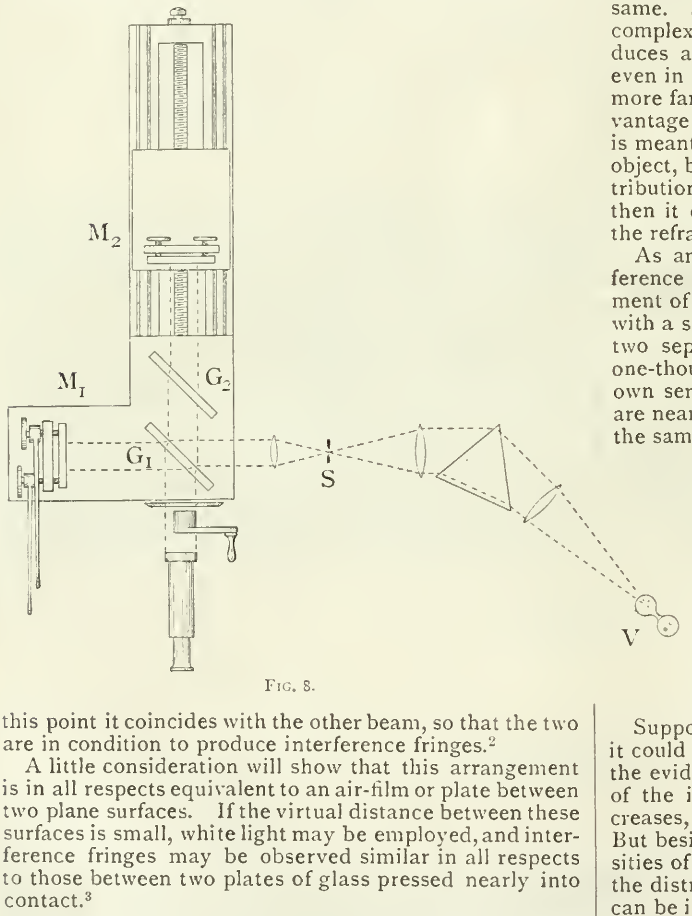

FIG. 8.

this point it coincides with the other beam, so that the two are in condition to produce interference fringes.[2]

A little consideration will show that this arrangement is in all respects equivalent to an air-film or plate between two plane surfaces. If the virtual distance between these surfaces is small, white light may be employed, and interference fringes may be observed similar in all respects to those between two plates of glass pressed nearly into contact.[3]

[1] The front surface of the plate G_1 is lightly coated with silver. The light which leaves the refractometer is a maximum where the thickness of the silver film is such that the intensities of the transmitted and reflected portions are equal. The silvering has another important advantage in diminishing the relative intensity of the light reflected from the other surface; and for this reason the thickness of the film may be advantageously increased, which permits also a more uniform surface. The ultimate ratio of intensities of the two pencils is not affected, for what is lost by transmission on entering the plate is made up by reflection on leaving it.

[2] One of the beams has to pass twice through the thickness of the glass plate G_1, and in order to equalise the two paths, a similar plate G_2 is introduced in the path of the other beam.

[3] If the plate G_1 be not silvered, the colours follow the same order as those of Newton's rings, but if the silvering be sufficiently heavy, the colours are complementary; this, if the plates G_1 and G_2 are exactly equal and parallel. Otherwise, the excess of path in glass of one of the pencils disturbs the order of colours by the effect of achromatism due to the dispersion of the glass, as was first pointed out by Cornu.

If, however, the distance exceeds a few wave-lengths, monochromatic light must be employed. In this case the fringes are in general invisible, unless they be viewed through a small aperture. If, however, the two surfaces are very accurately parallel, the fringes are always distinct, and it follows from the symmetry of the conditions that they are concentric rings. Their diameters increase as the square root of the order of the ring.

These rings are not formed at the surface of the mirrors (as is the case when the distance between them is small), but are perfectly distinct when the eye or the observing telescope is focussed for parallel rays.

In the preceding comparison between the refractometer and the telescope, microscope, or spectroscope, the "accuracy" has been increased at the expense of "definition." When, however, the object viewed is beyond the "limit of resolution" of the instrument, its form and distribution of light can no longer be inferred from that of the image. Thus, if the object be a disc, a triangle, or a double star, the appearance in the telescope is the same. Similarly in the spectroscope, a source of great complexity cannot be distinguished from one which produces a single spectral line. So that for such objects, even in the ordinary sense of the word "definition," the more familiar optical instruments cannot claim any advantage over the refractometer; but if by "definition" is meant not the actual resemblance of the image to the object, but the accuracy with which the form or the distribution of light in a minute source may be inferred, then it can be shown that all the advantage rests with the refractometer.

As an illustration of such an application of interference methods, let us consider the celebrated experiment of Fizeau, in which Newton's rings are observed with a sodium flame as source. The light, consisting of two separate systems of radiations differing by about one-thousandth in wave-length, each system produces its own series of interference fringes. When the surfaces are nearly in contact, the difference of path is very nearly the same for both systems, and the fringes coincide, and the clearness is a maximum. When, however, the difference of path reaches about 500 waves for one of the systems, it is a half wave more for the other; and the maxima of intensity of the one coincide with the minima of the other; hence at this point the fringes are faintest. But when the difference of path of the first system is about 1000 waves, it is a whole wave more for the second, and the fringes coinciding, there is again a maximum of distinctness. M. Fizeau has counted 52 such periods, corresponding roughly to a difference of path of 50,000 waves.

Suppose, now, that this double line were so close that it could not be resolved by the spectroscope; then from the evidence furnished by the variations in distinctness of the interference fringes as the difference of path increases, the duplicity of the line could be readily detected. But beside this, it can be shown that the relative intensities of the components, their distance apart, and even the distribution of intensities within the component lines can be inferred.

Thus it has been shown (*Philosophical Magazine* for September, 1892) that among some twenty radiations which were examined (though all give simple lines in the spectrum) the great majority are shown to be highly complex. Thus, the red hydrogen line is a double whose components have the intensity ratio 7 : 10, and whose distance is about a fiftieth of the interval between the sodium lines. Each component of the yellow sodium lines is itself a double whose components are in the ratio 7 : 10, and whose distance is about one-hundredth of that between the principal components. Thallium gives a double line whose components are in the ratio 1 : 2, at a distance of about a fiftieth of that of the sodium lines,

while each component has a small companion whose intensity is about a fifth of that of the principal lines, at a distance of about one three-hundredth of that of the sodium lines. The green mercury line is made up of a group of five or six lines, the strongest of which is itself double (or perhaps triple) the distance of the components, being less than a five-hundredth part of that between the sodium lines.

These distances, small as they are, can be measured within about a twentieth part, so that by this means it is possible to detect a change of wave-length corresponding to the ten-thousandth part of that between the two sodium lines.

The red line of cadmium is the simplest of all the radiations thus far examined, consisting of a single narrow line whose intensity falls off symmetrically according to an exponential law, its width (at the points where its intensity is reduced to half its maximum value) being only 0·002 (D_1–D_2). The green and the blue cadmium lines are also comparatively simple, and all three of these lines give interference fringes clearly visible at a difference of path of 100 mm., and under appropriate conditions they all satisfy the requisites for a definite and inalterable standard of length.

The most important of these conditions is that the radiating vapour be so rare that the molecules may vibrate freely; in other words, that the time occupied in the collisions between the molecules be so short relatively to that of the free path, that its influence in disturbing the free vibration may be neglected. Experience shows that in general this limit corresponds to a pressure of one or two thousandths of an atmosphere.

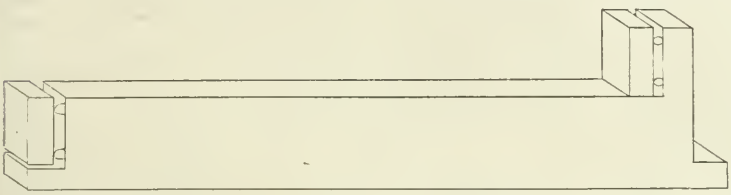

FIG. 9.

It may be noted that at atmospheric pressure—even when the radiating substance is introduced in quantity barely sufficient to colour a Bunsen flame—the greatest difference of path attainable is only one or two centimetres, whereas with mercury vapour in a vacuum tube interference fringes have been observed with a difference of path of 47 centimetres, or about 850,000 waves.

In order to make any practical use of these minute quantities for standards of length, it is necessary to employ an intermediate standard, such as that shown in Fig. 9, consisting of a bronze bar carrying two plane-parallel glasses, silvered in front, the distance between which can be compared on the one hand with the fundamental standard in actual use—the metre or the yard—and on the other with the length of a light-wave.

The former process is accomplished by moving the standard (whose length it is convenient to take at 10 centimetres) ten times through its own length, the coincidence and the parallelism of the surfaces being controlled at every step by the interference fringes in white light formed between these surfaces and that of the *reference plane* (the virtual image of the mirror MM in G_1, Fig. 8). The position of a fiducial mark on this standard is compared by means of two micrometer microscopes with the lines defining the standard metre at the first and last steps.

In the second process the only difficulty encountered is due to the very great disproportion between the length of a wave and that of the 10 centimetre standard, and the consequent difficulty in keeping the correct count of the very large number of waves which pass as the reference plane is moved from one surface to the other.

This problem has been solved in the following manner. Nine standards were constructed similar in all respects to that of ten centimetres, save that each succeeding one was half as long as the preceding. The last of the series is thus approximately 0·39 mm. long, corresponding to a difference of path of 0·78 mm. The number of waves in this distance in red cadmium light is 1212 plus a fraction, which is corrected by direct observation of the difference of phase of the circular fringes on the upper and the lower (front and rear) surfaces of the standard. This verification is also made with the green and the blue radiations.

It is important to note that the measurement of these fractions alone is sufficient to fix the whole number, even if there be an uncertainty of several waves. Thus, the relative wave-length of the three radiations being known, the number of green and of blue waves corresponding to the observed number of red waves can be readily calculated, as is shown in the following table:—

Wave-length.	Number of Waves. Observed.	Calculated.
μ		
0·64389	1212·34	1212·34
0·50863	1534·76	1534·76
0·48000	1626·16	1626·13

If the whole number assumed as the basis of this calculation were in error by one or more waves, there would be no correspondence between the observed and the calculated fractions. The length of this standard and the succeeding one are now compared as follows:—The two standards being placed side by side in the refractometer II on a fixed support, and I on a movable carriage, the reference plane (R, Fig. 10) is moved until it coincides with A, the lower (or front) surface of II, and the interference fringes in white light are adjusted to the proper distance and inclination by adjusting the inclination of the reference plane. Next, C, the lower surface of I is brought to coincidence with the reference plane, and similarly adjusted, and then all the adjusting pieces are released from the carriages, so that these rest undisturbed on the ways. This completes the *first stage* of the comparison.

Second Stage.—The reference plane R′ is now moved back till it coincides with D, the upper surface of I and

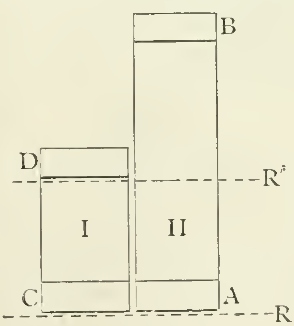

FIG. 10.

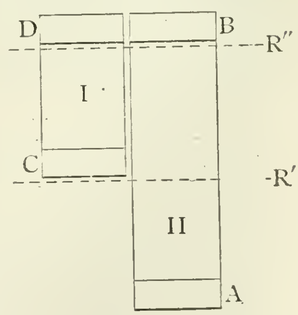

FIG. 11.

the adjustment of the interference fringes carried out as before.

Third Stage.—The standard, I, is moved back till its lower surface (C, Fig. 11) once more coincides with the reference plane, R′, and its inclination is again adjusted by the interference fringes.

Fourth Stage.—The reference plane is finally moved back till it coincides with D, the upper surface of I, and its inclination is again adjusted. If now the standard II

is just twice as long as I, the fringes will appear simultaneously on *both* upper surfaces, D and B.

The adjustment of the length of the standards is usually made to within a few waves, and the outstanding difference is measured by a compensating device.

This is furnished by the rotation of the compensating plate, G_2, Fig. 8. The plate is held in a metal frame which is supported at one end by a short thick rod firmly fixed to the bed. At the other end a delicate spiral spring is attached; the tension of the spring *twists* the rod through a minute angle, and thus alters the thickness of glass traversed by one of the interfering pencils. The other end of the spring is attached to a flexible cord passing over a pulley which is connected with a graduated circle. The angular motion is thus reduced about 100,000 times, and yet the proportionality is preserved.

Suppose the outstanding difference is ϵ a fraction of a wave-length known to within one or two tenths, then

$$\text{II} = 2\text{I} + \epsilon$$

and consequently the number of red waves should be $2 \times 1212{\cdot}34 + \epsilon$. This fraction is corrected by direct observation, as in the case of standard I, and the same control is furnished by the concordance of the results for the three colours; so that an error in the whole number of waves is well-nigh impossible.

The process of comparison and correction is repeated in the same way with the other standards, until we finally arrive at the whole number of waves and approximate fraction in the 10 centimetre standard. Up to this point the question of temperature and pressure is of minor importance, for the comparisons and corrections are made while both standards are under the same conditions; and being all made of the same material, it is sufficient to know that the temperature is the same for both. In the measurement of the fractions on the 10 centimetre standard, however, it is necessary to know the temperature and pressure with all possible accuracy, and it is also important that the comparison of this standard with the metre should be made, as nearly as may be, under the same conditions as that of the determination of the standard in light-waves.

The author having been honoured by an invitation from the International Bureau of Weights and Measures to undertake a series of experiments upon the lines here briefly indicated, the necessary apparatus was constructed in America, and shortly afterward installed in the Bureau International des Poids et Mesures at Sèvres.

Two complete and entirely independent determinations were made. These have not yet been completely reduced, but an approximate calculation gives for the number of waves of red light in one metre of air at 15° C. and 76 mm.

1st series	1553163·6
2nd series	1553164·6

The difference from the mean is half a wave, or about one fourth of a micron.[1]

From these results it follows that we have at hand a means of comparing the fundamental standard of length with a natural unit—the length of a light-wave—with about the same order of accuracy as is at present possible in the comparison of two metre bars.

This unit depends only on the properties of the vibrating atoms of the radiating substance, and of the luminiferous ether, and is probably one of the least changeable quantities in the material universe.

If, therefore, the metre and all its copies were lost or destroyed, they could be replaced by new ones, which would not differ from the originals more than do these among themselves. While such a simultaneous destruction is practically impossible, it is by no means sure that, notwithstanding all the elaborate precautions which have been taken to insure permanency, there may not be slow molecular changes going on in all the standards; changes which it would be impossible to detect except by some such method as that which is here presented

A. A. Michelson.

[1] The error in the determination of the *relative* wave-lengths of the three radiations is very much smaller, probably less than one twenty-millionth.

FURTHER NOTES AND OBSERVATIONS UPON THE INSTINCTS OF SOME COMMON ENGLISH SPIDERS.

Many of what would otherwise be most interesting anecdotes respecting the habits of spiders have been related by persons who, being unacquainted with the immense number of "kinds" of this group that there are in England, not to mention the rest of the world, have apparently considered that all needful information in the way of the animal's identity has been supplied by the simple statement that it is a spider.

Such anecdotes have of course a certain value, inasmuch as they furnish some general information respecting the instincts of the class as a whole. But to those who are anxious to compare together the instincts of individuals of the same or different species, genera, and families, who are anxious to acquire in short some little knowledge of the comparative psychology of the group, they are distressingly incomplete.

To remedy in part these deficiencies, to verify the experiments of others, and to make fresh observations upon some points that are open to dispute, I took the opportunity, during a recent visit to North Cornwall, of compiling a set of notes upon the habits of some of the commonest spiders in the neighbourhood.

In the following paper, which is based upon these notes, I have added some brief accounts of the webs, habitats, or general appearance of the spiders, so that those persons who are not acquainted with the animal by name, may yet, with but little trouble, ascertain what the species are that are under discussion.

Agalena labyrinthica.—This spider may be looked upon as the country cousin of the common house spider, *Tegenaria atrica*, which being essentially a lover of bricks and mortar, is found in lofts, disused rooms, &c., where it spins in corners and other angles a horizontal, triangular sheet of web, a familiar structure which must be associated in all minds with the word cobweb.

The snares of *Agalena* are essentially like those of *Tegenaria*, consisting of a short silken tube or funnel, one end of which is buried in the bush that the spider has chosen to build in, while the other opens upon, and is continuous with, a widely extended horizontal sheet composed of fine closely woven silken threads. During the daytime the spider, if cautiously approached, may usually be seen squatting at the entrance of her funnel. She is, however, remarkably wary, and this, coupled with her equally remarkable agility, makes the task of capturing her by no means an easy one. For, by means of the further open extremity of the tube, she can make her escape into the bush beyond. Wherever I have had an opportunity of observing this spider, I have noticed that it appears to have a special liking for furze bushes; and it seems reasonable to suppose that this selection of so prickly a site for the building saves the young and also the nest from destruction at the hands, or rather the noses and legs, of cattle.

Upon examining the *débris* of prey, with which the orifice of the funnel was usually strewn, I was surprised to find that it consisted more often of the remains of bees than of flies—generally, indeed, the limbs, wings, &c., were those of some species of Bumble-bees (*Bombus*). Being curious to see how the spider would manœuvre to overcome so redoubtable an adversary, I captured upon one occasion a small specimen of a bumble-bee and

placed it upon the snare. The *Agalena* immediately darted forth; but upon touching the insect with her fore-legs, quickly drew back as if to keep out of harm's way. Meanwhile, the bee, by making vigorous efforts to escape, had nearly succeeded in breaking away the web with which its legs were entangled—a fact of which the spider seemed well aware. For, rushing at it once more, she rapidly, and, by some dexterous movement that I could not follow, attached a thread either to the insect or to a portion of the web hard by, and then started to run rapidly round and round her prey, letting out the thread as she went, and literally winding the insect up. Having by this safe and satisfactory process speedily put a stop to all immediate likelihood of escape, and having also achieved the desired end of hampering the bee's movements, she again rushed two or three times at it, although still evidently bearing in mind the desirability of not coming to close quarters, and ultimately succeeded in inflicting a bite on one of its legs. From that moment all anxiety on her part respecting the probability of the escape of her prey seemed to disappear, for instead of keeping madly on the move, as she had done up to the time of dealing the wound, she quietly retreated to her funnel and sat down to wait. Nor was an explanation of this behaviour long in presenting itself. For the bee's struggles became more and more feeble, and in about one minute ceased altogether. There was very little doubt in my mind that this was attributable to poisoning: but to make sure that its quiescence was not due to exhaustion from its efforts, I took it from the web for examination, and found that it was to all intents and purposes dead, the only perceptible movement that it made being a slight twitching of the extremities of the antennæ. Whilst I was examining it I noticed the *Agalena* issue from her funnel and return to the spot where she had left her victim.

Subsequently to discover to what extent the spider's behaviour on this occasion was to be explained by her knowledge of the formidable nature of the bee, I placed a blue-bottle fly in the web of another specimen. The spider immediately rushed out, touched the insect with her fore-feet, and falling upon it without further delay, dragged it to the entrance of her tube, and proceeded to devour it.

As a further experiment I introduced an example of the drone-fly (*Eristalis*) into the web of a third example of this species; but, curiously enough, instead of instantly slaughtering the harmless insect, as the second one had the blue-bottle fly, this spider treated it with the same caution that the first had shown towards the bee. She did not, however, wind it up, but, keeping at a respectful distance, and watching for an opportunity, she ultimately bit it in the foot and killed it by this means in a few moments.

From these observations I think three conclusions may be legitimately drawn:—(1) That the first spider avoided contact with the bee for fear of being stung: (2) that the other mistook the *Eristalis* for a bee, as ninety-nine uninitiated human beings out of a hundred would also do; and (3) that the spider's bite rapidly compassed the death of the insects owing to the injection of poison. I wish to draw special attention to this last conclusion, not but that the others are more interesting, because Dr. McCook, when recently investigating the question of spider-venom, was inclined to reject the conclusion that the mandibular fluid of these Arthropods possesses any poisonous property.

His suggestion that the death of an insect results from mutilation caused by the bite clearly will not apply in the present instances where only a leg was bitten. For myself, I do not doubt that the fluid in question is poisonous, although probably in a varying degree to the insects upon which the spiders prey, and that the use of the poison is—as it also is, I think, in the case of scorpions—to put a speedy end to struggles, so as firstly to remove all chance of escape on the part of the prey, and secondly to lessen the probability of injury being done to the Arachnoid by a captive which might also be armed with jaws or stings.

When watching a couple of *Agalenas* pairing I was much struck by the extreme pertinacity with which the operation was carried on. As above stated, specimens of this species are usually exceedingly shy and very difficult to approach, but at this period both male and female seemed utterly oblivious to all their surroundings. They even permitted me to tear away portions of the web, and even to touch them without flinching. A cloud of tobacco smoke made them separate for a short time, but no sooner had it dispersed than they resumed operations as before. I repeatedly pulled the male from the female with my forceps; whereupon she would in alarm retreat to the further extremity of her tube, but he, seemingly, very little disconcerted by the compulsory interruption, would, when placed again in the web, quickly follow her, and presently both would appear again at the entrance of the tube, she lying perfectly passive and he hoisting her along with the patellæ of a pair of her legs grasped in his mandibles. Nor was she apparently much less eager than he, for on two occasions, when he was a little longer than usual in following her, she came forth herself apparently in search of him. It was noticeable that they invariably took up the same position in the same spot at the entrance of the tube, the female lying on her right side with her head towards the posterior extremity of the tube, the male standing over her facing the opposite way. A sketch made of them in this position agrees almost exactly with a figure that Dr. McCook has given of the attitude assumed under similar circumstances of the North American species, *Agalena nævia*. When I left this interesting couple the female had retired to the back of the tube, while the male sat on guard at the entrance. I say on guard, because when touched with my forceps he, instead of running away, raised high his forelegs, striking the instrument with them, and snapping at it with his mandibles. The way in which all the instincts for the preservation of the individual were overridden in this instance by the instinct for the preservation of the race brought very vividly before me the force of Prof. Lloyd Morgan's happy paraphrase of Shakespeare—"To breed or not to breed, that is the question."

Amaurobius similis.—This spider is very common in Cornwall, as elsewhere. It belongs to the same great group of tube-weavers as *Agalena*, spinning a tubular web in ivy, holes in walls, &c., and surrounding the aperture with a tissue of irregularly interlacing somewhat loosely woven threads which present a white thickened appearance, owing to the presence of flocculent tufts of silk that are produced by the agency of those interesting spinning organs, the *cribellum* and *calamistrum*. Like *Agalena* and *Tegenaria*, *Amaurobius* runs with agility on the upper surface of its web. *A. similis* is much smaller than *Agalena labyrinthica*, but does not appear to be so timid. I could never be sure of attracting *Agalena* to a vibrating tuning-fork, but *Amaurobius* would always come and even climb along the instrument. I have enticed this species from its hole by holding the vibrating-fork near the aperture, although not in contact with any part of the web. And all the specimens that were noticed on the external sheet of the web responded invariably when the vibrating-fork was held above them at a distance of about half an inch. But instead of running away from the instrument, or reaching up at it as the *Epeiridæ* do, *Amaurobius* moved excitedly about, apparently searching for the cause of the vibration. One specimen while thus searching came across and instantly seized the old dried-up carcase of a blue-bottle fly, as if perfectly satisfied with the result of its investigation. Another example, discovered away from her web, made no response whatever when the fork was held close to

her back. This circumstance, coupled with the fact that no specimen of this spider ever gave the smallest sign of knowing the direction whence the sound proceeded unless its web was actually touched with the tuning-fork, is in favour of Dr. McCook's view, that the *Epeiridæ*, which respond readily to a tuning-fork that is held near them, are only aware of the proximity of the vibrating instrument through the responsive vibration of the web. This may be the true explanation with regard to *Amaurobius*, but there are several reasons, as will shortly be seen, which lead me to think it is not so where the *Epeiridæ* are concerned.

Pholcus phalangioides, belonging to a group by itself, is a common spider in many parts of the south of England. It frequents kitchens and outhouses, where it spins a very untidy-looking web, composed of irregularly interlacing loosely-woven threads. The species cannot be readily mistaken for any other true British spider, on account of the extreme length and thinness of its legs. Owing to this peculiarity, it is probably largely responsible for the popular but erroneous idea that the Opiliones—the harvest-men or long-legged spiders *par excellence*—can spin webs. Whenever any part of the web of a *Pholcus* was touched with a vibrating tuning-fork, the occupant would come clumsily and leisurely up to the instrument, and when it was held close to the back of the spider, the latter would show its perception of the vibration by slowly lifting its legs. One specimen away from its web responded in exactly the same manner as the others did when hanging in the midst of their snares, thus showing that it is not the vibration of the web that informs this species of the proximity of the instrument.

Epeira diademata, *Meta segmentata*, and *Zilla x-notata*, are three very common spiders belonging to the group of Orb-weavers. The first-named—the common garden or cross-spider of England, one of the largest of our species—is known to every one. *Meta segmentata*, too, is very abundant, spinning its web in hedges and bushes; it may be easily recognised from *E. diademata* by its much smaller size and more graceful build. *Zilla* is more like *Meta* than *Epeira*, being a smallish, rather graceful species, which spins its web very commonly in the angles of windows, &c. The structure of its web also affords another clue to its identity, for while in *Epeira* and *Meta* the snare is a complete orb, the concentric lines extending across all the radii from the centre to the circumference, in *Zilla*, as a very general rule, two of the inter-radial spaces in the upper half of the web are not crossed by the concentrices: the circle of the web thus lacks one sector, and the resulting triangular space is traversed by a free radius, which is continued beyond the circumference of the snare, and connects its centre with a second small irregular web, which is spun in a crevice or beneath some leaf.

Like most other spiders these three species will usually come to a vibrating tuning-fork, if the web be touched with it. And if it be held over the centre of the web where the spider is hanging, the three will readily respond to the sound; but not in the same way. As Mr. and Mrs. Peckham and Prof. Boys[1] have shown, an adult *Epeira diademata* raises its forelegs and snatches at the instrument, while *Meta*[2] *segmentata* instantly drops by a thread from her snare; but *Zilla*, so far as my experience goes, instead of dropping like *Meta*, nearly always climbs quickly along the free radius back to the upper web. One example, however, repeatedly dropped from its web, and two others, one adult and one young, moved excitedly about as if in search of the cause of the sound, exactly as described in the case of *Amaurobius*. Curiously enough the sound affects the examples of *diademata* differently according to their age. Thus quite small examples drop by a thread, but half-grown examples either drop as the young do, or strike at the fork like the adults. It appears therefore from these facts, that as a general rule the small English Epeiridæ fear the sound of a vibrating tuning-fork, while the large ones do not. What is the explanation of this? Prof. Boys, who has previously noticed this same fact in connection with *E. diademata* and *Meta*, thinks that it is perhaps to be explained on the grounds that the vibrating tuning-fork is mistaken for an approaching wasp—an insect which, to use Dr. McCook's words, "is the most persistent enemy of spiders." But a full-grown *E. diademata* is too formidable an opponent for a wasp to attack, and it seems well aware that anything buzzing can be overcome and eaten, or at least repulsed. Not so, however, is it with a *Meta*. A wasp can take one of these small spiders out of its snare while still on the wing, and the spider's life depends upon the quickness with which it can perceive the approach of its enemy and act upon the perception by dropping out of harm's way.

This ingenious suggestion is further borne out by the behaviour of *Zilla* and of the young *diadematas*, for these spiders would have no more chance against a wasp than *Meta* has. Moreover, my friend Mr. Henderson, of Madras, has informed me that he has repeatedly seen examples of a common Indian house spider[1] drop from their webs at the approach of the mason-wasps.

Such a habit, then, of falling or running away would clearly give a spider that possessed it an advantage in life over others of the species in which it was not developed, and the elimination of the latter and the survival of the former, with the consequent chance of breeding, would foster the habit and bring it to the state of perfection in which we now see it.

On the other hand, the loss of the habit in the adult *E. diademata*, may perhaps be explained on the hypothesis that the act of dropping entails the expenditure of energy in the form of waste of silk and of muscular tissue; moreover, it might at the same time on occasions lead to the escape of an insect that would have served for prey if the spider had remained in *statu quo*. The two instincts are seen in a state of transition in half-grown *diadematas*. But the acquired one of fearlessly fighting the enemy would be prevented from appearing too early in life by the destruction of those individuals which, with over-confidence on their growing powers, stayed in the web when they ought to have dropped from it; or, in other words, the runaway instinct would be preserved as long as the spider was too small to cope with a wasp.

Another interesting question connected with this behaviour of the Epeiridæ is the means whereby the vibration of the fork is perceived. The obvious answer is that the sound is heard. But Dr. McCook has recently objected to this explanation on the grounds that the Lycosidæ, which spin no web, and which, in Dr. McCook's opinion, have more need of an auditory sense than the Epeiridæ, make no response when the vibration is brought near them.

It has been objected (*Ann. Mag. Nat. Hist.* Ser. 6, viii. p. 103), however, to this opinion of McCook's that the Epeiridæ which spin their webs in places where flies are likely to be caught, must of necessity at the same time expose themselves to the attacks of wasps. We can therefore imagine that it is of the highest importance to them to be able to perceive the approach of their enemy—of more importance to them, in fact, than to those spiders, which like the Lycosidæ spin no exposed and conspicuous snare, and are therefore more likely to escape the notice of the wasps.

To account for the behaviour of the Epeiridæ when a vibrating fork is brought near them, Dr. McCook has suggested that the vibration of the instrument causes

[1] Nature, vol. xliii. pp. 40-41.

[2] This is probably the small unidentified orbicular spider that Prof. Boys speaks of.

[1] Mr. Henderson kindly procured examples of this spider for me, and they proved to belong to the genus *Pholcus*.

the threads of the web to vibrate in turn, and that the spider is informed of the nearness of the instrument by the delicate sense of touch in the feet. But so far as my experience goes this hypothesis is not sufficient to account for the facts; for it is difficult to understand how the sense of touch in the feet can merely by being in contact with the threads, which by hypothesis are in a state of vibration, inform the spiders of the position of the fork and of the direction whence the sound proceeds. For of this, to judge by their actions, they appear to have a full knowledge. For instance, one adult example of *E. diademata* that I observed, responded in the manner above described when the fork was held over her back; but when the instrument was brought towards her ventral surface on the other side of the web she drew her body away from it, standing as it were on the tips of her toes. Again, when the fork was brought from below to within a distance of an inch and a half or two inches of a *Meta* suspended by a thread from her web, she instantly dropped again. In this case it is hard to believe that from such a position the fork could throw the web into a state of vibration. On the other hand, no example of the Epeiridæ could ever be attracted along one of the radii of the web, however close the fork was held to it, unless the two were actually in contact. In view of these facts, it seems to me probable that Mr. and Mrs. Peckham's explanation of the behaviour of the Epeiridæ—namely, that they hear the vibration—is the true one.

R. I. Pocock.

NOTES.

The Royal Society's medals have this year been adjudicated by the President and Council as follows:—The Copley Medal to Sir George Gabriel Stokes, Bart., F.R.S., for his researches and discoveries in physical science; a Royal Medal to Prof. Arthur Schuster, F.R.S., for his spectroscopic researches, and his researches on disruptive discharge through gases and on terrestrial magnetism; a Royal Medal to Prof. Harry Marshall Ward, F.R.S., for his researches into the life history of fungi and schizomycetes; and the Davy Medal to Messrs. J. H. van't Hoff and J. A. Le Bel, in recognition of their introduction of the theory of asymmetric carbon, and its use in explaining the constitution of optically active carbon compounds. Her Majesty the Queen has been graciously pleased to approve of the award of the Royal Medals. The medals will, as usual, be presented at the anniversary meeting on St. Andrew's Day (November 30). M. Le Bel has promised to attend in person, and it is hoped that all the medallists will be present. The Society will dine together at the Whitehall Rooms on the evening of the same day.

By the death of Sir Andrew Clark, on the 6th inst., the medical profession has lost one of its most prominent members. The Royal College of Physicians has to mourn the decease of its President, and, outside the faculty, a large and distinguished section of the community is affected by it. Sir Andrew was born on October 28, 1826, at Aberdeen, and pursued his medical career there and at Edinburgh. Subsequently he entered the Royal Navy as a surgeon, and, after making a few voyages, became pathologist to the Royal Naval Hospital at Haslar. There he met Prof. Huxley, who was then professor of biology at the hospital school. In 1853 he accepted the curatorship to the museum of the London Hospital, and was afterwards appointed pathologist to the hospital, then lecturer on physiology, and in 1866 full physician. After this Sir Andrew rapidly came to the front, and from the first his connection was composed largely of men distinguished in science, art, and literature. In 1883 Her Majesty recognised his position in the profession, and his services to medical science, by conferring upon him the honour and title of a baronetcy. Five years later he was elected to succeed Sir William Jenner as President of the Royal College of Physicians, an honour that he valued even more highly than Royal favours. He was a Fellow of the Royal Society, an LL.D. of Aberdeen, Cambridge, and Edinburgh, and honorary M.D. of Dublin. The respect in which he was held is shown by the influential and representative character of the assembly at a commemorative service in Westminster Abbey on Saturday. The pall-bearers included the Prime Minister, Sir Henry Acland (Regius Professor of Medicine at Oxford), Sir James Paget (Vice-Chancellor of London University), Mr. John Whitaker Hulke (President of the Royal College of Surgeons), Sir Richard Quain (President of the General Medical Council, representing by request of the Provost the University of Dublin), and Sir Edward Sieveking. Following these, with the officers of the Royal College of Physicians, came representatives of the Universities, State departments, and various institutions. Prof. Clifford Allbutt attended for Cambridge, Sir Joseph Fayrer for Edinburgh, Dr. Farquharson, M.P., for Aberdeen, Mr. J. N. Dick for the Navy Medical Department, Sir William Mackinnon for the Army Medical Department, Dr. Thorne Thorne for the Medical Department of the Local Government Board, Sir William Flower for the British Museum, and Prof. Michael Foster for the Royal Society. Among the large congregation were Prof. Huxley, Sir Spencer Wells, and Sir Walter Phillimore. Honoured in life, Sir Andrew Clark's memory will be cherished by all acquainted with his wonderful energy, devotion to duty, and self-sacrifice—attributes worthy of emulation by all followers of his noble profession.

The death of Dr. H. A. Hagen, a well-known entomologist is announced from New York. He was born in Königsberg in 1817, and became an assistant to Agassiz in 1867. Three years later he was appointed Professor of Entomology at Harvard College. It can truly be said that his works furnish a monument to his memory, for he made more than four hundred contributions to scientific literature.

We have to record that Mr. A. Reckenzaun died on November 11, at the age of forty-three. His name is familiar in connection with papers on accumulators, electric traction, and electric locomotives, for certain of which he was awarded medals by the Society of Arts and the Institution of Electrical Engineers.

We regret to learn from Sydney of the death of Dr. George Bennett, a distinguished naturalist, and the author of "Wanderings in New South Wales" and other works. He was ninety years of age.

The death is announced of Mr. J. G. Barford, the author of a number of papers on physiological chemistry.

In January next, the Botanical Society of Italy will take over the *Nuovo Giornale Botanico Italiano*, at present edited by Prof. T. Carnel, and publish it as the official organ of the Society. No modifications will be made, however, in the character of the journal, which will continue to be issued in quarterly numbers.

A meeting of representatives of technical schools was held at Manchester on the 4th inst., and it was resolved "that it is desirable that an Association of Technical Institutions be formed." With a view to formally constituting the proposed Association, a meeting will be held at the Society of Arts, on Friday, January 26, 1894.

The new institute of science, art, and literature, established by the corporation of Carlisle at a cost of about £20,000, was opened by the mayor of that city on November 8. The institute includes a museum, a school of science and art, and a free library. In addition to a valuable collection of antiquities, the

museum contains a good collection of stuffed birds, the late Prof. Harkness's collection of fossils, and a number of specimens of rocks of the English Lake district.

It is reported that a seam of good coal has been discovered at Port Jackson, at a depth of 3000 feet below the surface.

At the second meeting of a conference of the General Lighthouse Authorities of the United Kingdom and their engineers, together with representatives of the Admiralty and Board of Trade, held at the Trinity House on November 10, it was decided to publish in the official list of lights the candle-power of each light as determined by the engineers. By this means mariners will be informed of the relative illuminating powers of all the principal lights on the coast.

A corporation has been formed at Chicago for the purpose of creating and sustaining a museum (says the *American Naturalist*). Prof. F. W. Putnam has been appointed managing director of the scheme. It is expected that he will organise the museum into departments, and will place over each a competent head, who will make it a medium of original research as well as of exhibition.

At the annual meeting of the New York Mathematical Society, to be held on December 28, Prof. Simon Newcomb will deliver an address on "Modern Mathematical Thoughts."

The fifth of the Gilchrist Lectures, in connection with the Bethnal Green Free Library, will be given on Thursday, 23rd, in the Great Assembly Hall, Mile End Road, by Dr. R. D. Roberts, his subject being "The Evolution of the British Isles."

The Christmas course of lectures for juveniles will this year be delivered at the Royal Institution by Prof. Dewar. The subject will be "Air, Gaseous and Liquid," and the first lecture will be delivered on Thursday, December 28.

The following science lectures will be delivered at the London Institution during the ensuing session: "Birds—Ancient and Modern," by Dr. B. Bowdler Sharpe; "When and Why an Electric Spark Oscillates," by Prof. C. V. Boys; "Crabs," by Prof. W. F. R. Weldon; "The Pond and its People," by the Rev. Dr. Dallinger. Mr. Shelford Bidwell will discourse on "Some Optical Phenomena"; Mr. J. J. H. Teall, on "The Life History of a Mountain Range"; Dr. Klein, on "Cholera," and Prof. Vivian Lewes, on "The Chemistry of Cleaning." The Christmas course for juveniles will be given by Mr. H. J. Mackinder.

In an interesting report, presented to the Department of Agriculture of New South Wales, Mr. A. Sidney Oliff, the Government Entomologist, deals with the injuries inflicted on the sugar-cane crops in the Clarence River district by the ravages of insects. He finds the larger part of the injury to be due to the attacks of the larva of a moth, the sugar-cane moth borer, *Nonagria exitiosa*, but that its increase is kept in check by two minute hymenopterous parasites, both hitherto undescribed; one, *Apanteles Nonagriæ*, belonging to the Ichneumonidæ, the other, *Euplectus Howardi*, to the Chalcididæ.

Two recent publications of the Board of Agriculture deal with experiments in checking potato disease in the United Kingdom and abroad. The history and cause of the potato disease are first explained, and a great variety of experiments are described in detail. They form a useful manual for agriculturists in their fight against the *Peronospora*.

Mr. J. H. Hart, the Superintendent of the Royal Botanic Gardens, Trinidad, has recently been successful in transporting to Nicaragua a selection of the best varieties of Trinidad "cacao." Cacao seed soon loses its vitality, and can only be safely transported long distances by placing it in a suitable position to germinate and grow on the voyage. On April 25 of this year, Mr. Hart left Trinidad with a number of specially-prepared cases containing plants, and seeds planted on the day of departure. The boxes in which the seeds were sown had not glass roofs, but were strongly latticed and covered with a movable sail-cloth cover which could be easily and rapidly fastened or unfastened, to give light, or to protect from wind, rain, and sun. A frame covered with wire-netting was fastened inside each case, so as to press upon the surface of the soil to prevent it shifting and causing the seeds to be disturbed. The seeds germinated ten days after planting, and on June 10, Mr. Hart reached his destination with more than 26,000 healthy plants, which were successfully put out in nurseries. A number of cacao seeds were sown at Nicaragua to develop during the return voyage, and, upon arriving at Trinidad, good healthy plants were obtained from ninety-eight per cent. of the seeds planted. These plants included two species entirely new to Trinidad, and their introduction may eventually prove of great benefit to the colony.

Dr. Karl A. von Zittel, Professor of Palæontology in the University of Munich, has at length completed the final volume of his comprehensive "Handbook of Palæontology." The first three volumes are already familiar to all students of palæontology, the fourth volume is devoted to the group of Mammalia. In the *Geological Magazine* for the months of September, October, and November, Dr. G. J. Hinde gives a translation of the concluding chapter, entitled, "On the Geological Development of the Mammalia." The palæontological record from Triassic to recent time is there summarised for the various continents, and Prof. von Zittel advances many additional data in support of Huxley's opinion that the *four* zoogeographical kingdoms of A. R. Wallace, the Palæarctic, Nearctic, Ethiopic, and Indian, form in point of fact but *one* great area of development—the Arctogean. This is the youngest of three areas of mammalian development; the oldest is the "Australian," which was separated from other continents as early as Mesozoic time, while the "South American" area dates as far back as early Tertiary.

A paper, by Mr. C. T. Simpson, on some fossil Unios and other fresh-water shells from the drift at Toronto, Canada, is contained in the Proceedings of the U.S. National Museum, vol. xvi. Mr. Simpson finds that the Unio fauna of the Mississippi Valley is remarkably distinct, being nearly related only to a part of that of North-Eastern Asia. It can be traced back to the Laramic group of the Cretaceous in an almost unbroken line of species. Glacialists will be interested in the following conclusion:—"The theory founded by Agassiz and elaborated by Dawson, Upham, Gilbert, Tyrrell, and others, that during the glacial period the archæan region of Canada was elevate from 1,000 to 2,000 feet above its present level, and that it was covered with an ice mantle from 3,000 to 6,000 feet thick, a mantle which in the eastern part of the United States extended down to latitude 38° or 40°; that in the Champlain period which followed there was a subsidence over this area, during which great lakes were formed by the melting ice, whose northern shores were the yet remaining wall of ice, and whose southern borders were the land that sloped northward; and that they drained into the Mississippi system, is most strongly confirmed by the evidence of these fossil Unios, and by every fact of the distribution of the Naiades in this general region to-day. It is believed that the entire system of the present Great Lakes was united, and that at one time it covered a considerable part of Lower Michigan, and extended well into Ohio, Indiana, and Illinois."

The great importance attaching to an accurate knowledge of the precise instant at which an earthquake shock is felt at a

given station, has led Dr. A. Cancani, of the Rocca di Papa Geodynamic Observatory, to construct a seismograph which registers the time of the occurrence by an instantaneous photograph of a chronometer. From its description in the November number of *L'Elettricista*, it appears that the face of the chronometer is photographed by the light of an incandescent lamp, lighted for about a quarter of a second by a current established automatically by the shock. A lever of the first order carries on one arm nine small vessels containing potassium bichromate solution, whilst the other arm rests on the armature of an electro-magnet. The latter is connected to all the seismoscopes of the observatory, any one of which may establish the circuit and cause the armature to be attracted down. This raises the bichromate vessels and immerses the zinc-carbon couples fixed above them, thus supplying the lamp with a current. The closing of the circuit releases the lever, and the apparatus is automatically rearranged for the next shock.

AN improved form of rotary air-pump has been constructed by Herr F. Schulze-Berge, and is described and illustrated in *Wiedemann's Annalen*. That chief difficulty in rotary air-pumps, the air-tight junction between the rotating and the stationary parts, has been overcome in a manner which is simple, ingenious, and very efficient. The tube from the vessel to be exhausted is led through the bottom of an inclined cylindrical vessel filled with mercury. A somewhat larger tube, forming the shaft of the rotating pump, reaches nearly to the bottom of the vessel, and surrounds the end of the first tube in such a manner that there is free communication between the two tubes, whilst all communication with the outer air is intercepted by the mercury. This mercury stuffing, while causing no friction, is found to be effective even at the highest vacua. The rotating tube is surrounded by another, which embraces the cylindrical vessel, and revolves on it with an air-tight junction formed by an ordinary stuffing-box or another mercury junction. The interior of this outer tube is exhausted by an auxiliary pump, so as to keep the difference of level in the mercury vessel small. The shaft carries a circular tube rotating in an inclined plane, about one-third of the tube being filled with mercury. This mercury forms a kind of piston for drawing the air out of the inner shaft, and driving it into the outer one and into the auxiliary pump. The tubular ring is interrupted in one place by a mercury valve, consisting of a U-tube or two concentric tubes parallel to the shaft, one of which communicates with the inner shaft and the recipient, the other leading into the space between the two shafts. In an improved form of the apparatus two concentric tubular rings are used, so that the space to be exhausted is separated by the mercury valve from another exhausted to nearly the same extent. The vacua obtained with this pump are beyond the limits of accurate measurement by McLeod's apparatus, and they are obtained much more rapidly than by other mercury pumps. A pump with rings of 60 cm. diameter and a capacity of 0·9 litre could be driven mechanically at a speed of 15 revolutions per minute. The inventor is constructing a pump of 8·5 litre capacity for industrial purposes.

THE *Electrician* contains a description of a method for comparing the capacities of two condensers when they are of so small capacity that it is impossible to obtain, by the ordinary direct deflection method, readings sufficiently large to be accurately measured. The apparatus used consists of an electrically driven tuning-fork, performing about 280 double vibrations per second, one limb of which is provided with a platinised style vibrating between two light platinised springs, whose movements are damped so that their individual vibrations may not conflict with those of the fork. These springs are adjusted relatively to the style on the fork, so that contact shall be made with them alternately, but that when the fork is at rest it shall not be in contact with either. One spring is connected to one pole of a battery, the other to one terminal of a galvanometer, and the fork to one terminal of the condenser, the other terminals of the battery, galvanometer and condenser being connected together. When the fork vibrates, it first charges the condenser, and then discharges it through the galvanometer. The succession of impulses being so rapid (280 per second), the effect upon the galvanometer is nearly that of a continuous current, and the deflection is steady. It is possible with this arrangement to measure the capacity of a person who is insulated from the floor, and to note the increase of capacity due to the approach of other (uninsulated) persons to him.

L'Elettricista for November contains a paper, by Signor G. Brucchietti, on the effect of the absorption of hydrogen on the thermo-electric power and electrical resistance of palladium. The author finds that the resistance of a wire of palladium containing hydrogen increases in proportion to the quantity of hydrogen absorbed, and that when it is saturated the resistance is 1·55 times as great as it was before being charged with the hydrogen. If the same wire is repeatedly saturated with, and freed from hydrogen the resistance seems to tend towards a constant value (whether hydrogen is present or not), which is intermediate between the resistance before being charged, and that after being charged for the first time. In the experiments on thermo-electric force the author used a couple consisting of palladium and nickel, and found that the thermo-electric force of this couple increased with the amount of hydrogen absorbed by the palladium. When the palladium is saturated, the thermo-electric force of the couple is 1·66 times as great as it was before the palladium was charged. In a thermo-electric couple formed of charged and uncharged palladium the current at the cold junction was found to go from the charged to the uncharged palladium. This result is contrary to that obtained by Knott, and the author supposes the divergence to be due to impurity in one or other of the samples of palladium employed.

AN exhaustive study of a problem belonging to the mathematical side of chemistry appears in the current number of the *Annales de Chimie et de Physique*. Here M. Lemoine investigates the influence of heat, unaffected by that of light, on the reactions which take place in aqueous solutions containing ferric chloride and oxalic acid. When these substances are present in equivalent proportions, the interaction is irreversible, and proceeds according to the equation, $2FeCl_3 + H_2C_2O_4 = 2FeCl_2 + 2HCl + 2CO_2$. At any temperature the rate at which decomposition takes place is found to follow the well-known law of mass action, which states that the amount of substance which is being decomposed at any instant is proportional to the amount of unchanged substance contained in unit volume of solution. The rate of change, concentration remaining the same, is found to vary to a most marked extent with variation in temperature. Thus at 100°, in one hour ·16 of the original amount of substance was decomposed, whereas at ordinary temperatures after six years only ·019 equivalents had reacted. The presence of water accelerates the velocity of change according to a law which varies slightly with the temperature, a slight excess of oxalic acid accelerates the rate, a large excess of oxalic acid or of ferric chloride retards it. Excess of concentrated hydrochloric acid almost completely arrests the reaction. The effects which these and other materials exert upon the course of the simple reaction, the author studies both by chemical and thermochemical methods, and shows that they may be explained by the occurrence of secondary reactions. The communication, which extends over more than 100 pages, serves to give some idea of the patient labour involved in elucidating the mechanics of what appears at first sight to be a comparatively simple case of chemical decomposition.

The Calendar of the University College of Nottingham for the thirteenth session, 1893–94, has just been issued.

A "Bibliography of the Chinookan Languages" (including the Chinook jargon) has been prepared for the Bureau of Ethnology, Washington, by Mr. J. C. Pilling.

Messrs. Perken, Son, and Rayment have published the eighteenth edition of a little book on "Intensity Coils," and the second edition of "The Magic Lantern: its Construction and Use." Both books are suited to the wants of the scientific amateur.

Mr. Albert F. Calvert presents, in his "Mineral Resources of Western Australia" (George Philip and Son), an array of facts of particular interest to the capitalist and emigrant. Beneath the surface of that country lie belts and reefs of gold-bearing rocks sufficient to satisfy the most avaricious, and Mr. Calvert is desirous that the profuseness of these and like mineral deposits should convince people that the country offers "mighty possibilities" to enterprise.

Dr. M. C. Cooke's "Romance of Low Life among Plants," published by the Society for Promoting Christian Knowledge, is an interesting and very readable book on cryptogamic vegetation. Though written in language "understanded of the people," and full of romantic beliefs connected with plants in a bygone age, scientific accuracy is not sacrificed, and scientific words are not strictly tabooed, as they usually are in the diffuse books designed for the popular palate. A larger number of illustrations would render the book still more interesting and valuable.

Dr. A. R. C. Selwyn, C.M.G., F.R.S., the Director of the Geological Survey of Canada, has had a catalogue prepared of the fine stratigraphical collection of Canadian rocks exhibited by the Survey Department at the Columbian Exposition. The collection comprised 1500 specimens, illustrating all the formations known to occur in the Dominion of Canada, from the Laurentian to the Pleistocene. Mr. W. F. Ferrier gives a few explanatory notes with regard to the rocks represented in the collection.

If the number of books published on a particular subject can be regarded as an indication of the interest taken in that subject, we are led to the gratifying conclusion that physical laboratories are rapidly increasing. Books dealing with practical physics are constantly being published, and the last received by us—"Practical Work in Heat," by Mr. W. G. Woollcombe (Clarendon Press)—shares the generally excellent character of works of its kind. It is now believed by all men of science that physics cannot be properly taught by lectures alone, any more than chemistry, and the belief is slowly but surely causing our schools and colleges to give facilities for such necessary practical work. Mr. Woollcombe's book includes sections on thermometry, expansion, calorimetry, evaporation, and radiation. Excellent experiments are described in each section, and their performance does not necessitate the use of expensive apparatus. In fact, the book contains a practical course in heat that we should like to see introduced into every school which includes physical science in its curriculum.

Compounds of carbon monoxide with potassium and sodium respectively have been obtained by M. Joannis, by the action of gaseous carbon monoxide upon solutions in excess of liquefied ammonia of the peculiar compounds which potassium and sodium form with ammonia. M. Joannis has for several years been investigating the nature and reactions of these latter compounds, potassammonium and sodammonium, and the results of his researches have been referred to in previous notes (see Nature, vol. xliii. p. 399, and vol. xlv. p. 158). The reactions which occur between these substances and carbon monoxide are of a most interesting character, throwing light as they do upon the nature of the dangerously explosive compound of potassium and carbon monoxide which formerly produced such deplorable accidents during the commercial production of metallic potassium by the method of Brunner. A considerable number of investigations have been carried out with the object of obtaining a complete knowledge of this explosive substance, but the results arrived at can scarcely be termed concordant. Most of the investigators agree in assigning to it the simple formula KCO, but the descriptions of its properties are very diverse. Liebig and likewise Lerch describe it as a black powder, while Brodie endows it with a red colour. The latter chemist found it to react in a most violent manner with water, while Liebig's substance was much more gentle in its demeanour towards that solvent, and actually permitted of the application of a moderate heat with no more serious result than quiet inflammation. More recently Nietzki and Beuckiser have described it as not only explosive but as detonating, when exposed to the moist atmosphere, under the influence of the least concussion in its neighbourhood. The potassium compound now described bears most resemblance to the unstable substance of Brodie and of Nietzki and Beuckiser, although differing in several particulars. The analogous sodium compound does not appear to have been previously obtained.

When dry carbon monoxide is allowed to bubble through a solution in liquefied ammonia of potassammonium, the blue substance of the probable composition $(KNH_3)\,n$ produced by dissolving metallic potassium in liquefied ammonia, the containing vessel being cooled to $-50°$, the deep blue colour gradually diminishes in intensity, and is eventually supplanted by a pale rose tint, the attainment of which signifies the completion of the interaction. Upon removal from the cooling mixture the liquefied ammonia gradually vaporises, depositing as it does so a rose-coloured powder which upon analysis proves to be pure potassium carbonyl KCO. When left undisturbed in a sealed tube for some time this pink powder darkens in colour, then answering very closely to the description of Brodie's substance. It cannot be heated to the temperature of boiling water, explosion ensuing considerably below that temperature. Detonation likewise occurs if the merest trace of air is admitted, and instantly when touched with a drop of water. Air and water both appear to act by causing such an elevation of temperature by their reaction with a small portion as to bring about sudden decomposition of the whole. It is, however, possible to study the reaction with water by admitting a drop of that liquid into an exhausted tube containing potassium carbonyl in such a manner as not to come into direct contact with the substance; the aqueous vapour then slowly reacts with the apparent production of deliquescence and the eventual formation of a yellow viscous liquid. The nature of this liquid is reserved for a future communication.

Sodium does not resemble potassium in directly uniting with carbon monoxide. Sodammonium $(NaNH_3)n$, is, however, readily decomposed by carbon monoxide with formation of sodium carbonyl, NaCO, a substance which may be isolated in a manner similar to that employed for the isolation of the potassium compound. It is a pale lilac-coloured substance which is powerfully explosive like its potassium analogue. Detonation ensues under the influence of small quantities of either air or water. Under the influence of heat its colour darkens, no gas is evolved, but about 90° sudden explosion occurs, and with such force that no glass has yet been found to withstand it. It also explodes like the potassium compound under the influence of percussion, although not quite so readily as the latter substance. The nature of the changes occurring in

the explosion by percussion were ascertained by performing the reaction in a sealed tube of strong glass, also containing a few glass beads. The rattling of the beads was sufficient to induce explosion, and in one experiment out of a large number the tube remained intact. It was found that the products were all solid substances. The main reaction proceeds in accordance with the equation $4NaCO = Na_2CO_3 + Na_2O + 3C$. A small quantity of sodium cyanide was also produced. When a drop of water is introduced into a similar tube detonation immediately occurs, and the whole tube is filled with a red flame, the colour of which may perhaps be accounted for by the fact that a considerable quantity of hydrogen gas is liberated. The other products of the reaction are sodium carbonate, free carbon, and a small proportion of carbon monoxide. Water vapour, however, reacts in a quiet manner, as in the case of potassium carbonyl, the substance successively changing colour to brick-red, reddish-brown, and dark violet, until at length a viscous liquid of a deep red colour is produced, whose nature, together with that of the liquid derived from the potassium compound, M. Joannis is now investigating.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include a specimen of the fine Nemertine *Cerebratulus roseus*, now first recorded for the British Isles. There are clearly hosts of interesting forms in the deeper water off the Devon and Cornish coasts, if only we had a stout steamboat from which to dredge this rich locality. The floating fauna has not been rich, owing to the prevalence of northerly and easterly winds. The presence of *Radiolaria*, in spite of this, has been an interesting feature. Terebellid and Polynoid larvæ, *Sagitta*, and a few Ophiuroid *Plutei* have also been observed.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by Mr. James Kendal; a Hairy-nosed Wombat (*Phalascomys latifrons*, ♂) from South Australia, two Marabou Storks (*Leptoptilus crumeniferus*), a White-necked Stork (*Dissura episcopus*) from West Africa, a Javan Adjutant (*Leptoptilus javanicus*) from Java, presented by Mr. E. W. Marshall, F.Z.S.; a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Mrs. B. E. F. Stevens; two and three Hedgehogs (*Erinaceus europæus*) British, presented respectively by Mr. W. Chatterton and Mr. A. S. Bird; two Herring Gulls (*Larus argentatus*) British, presented by Mr. B. Tremble; a Blossom-headed Parrakeet (*Palæornis cyanocephalus*, ♂) from India, presented by Mrs. Osmond Barnes; a White-handed Gibbon (*Hylobates lar.*, ♀) from the Malay Peninsula, deposited; a Mona Monkey (*Cercopithecus mona*, ♂) from West Africa, two Lapwings (*Vanellus vulgaris*), a Common Curlew (*Numenius arquata*) British, purchased; three Dingoes (*Canis dingo*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

BROOKS'S NEW COMET (1893*c*).—In the *Astronomical Journal* (No. 306), Prof. E. E. Barnard briefly describes a photograph of this new comet, which he was able to obtain with a 6-inch Willard lens. The exposure was made under conditions not very conducive to good results, owing to the low position of the comet and the presence of the zodiacal light. The negative exhibits, however, many points of interest, and its characteristic features are described as similar to those shown in the photographs of Swift's comet 1892 I. Prof. Barnard's description is as follows:—"The plate shows the tail to a distance of 3½°. This tail irregularly divides into two slightly divergent branches. There are two narrow straight rays springing out from the head on opposite sides, and nearly symmetrical with the main tail. The north ray, which seems to leave the region of the nucleus, is inclined to the body of the comet by about 45°; the southern, which leaves the comet 10′ or 15′ back of the head, is inclined about 30°. They are both about ½° long. There are faint evidences of several other rays from the southern side of the comet."

BIELA METEORS.—The return of the "Andromedes" this year is looked forward to with special interest, owing to their great abundance last year. It will be remembered that in 1892, instead of arriving on November 27 or 28, as was expected, the maxima occurred about the 23rd, or four days in advance of the predicted time, so that observers this year must be on the *qui vive* early. The director of the Pulkova Observatory, M. Bredichin, accounts for this retrograde motion by supposing it to be caused by the perturbations of Jupiter, which during 1890 were very great. Besides a retrogradation of the node amounting to 4°, the inclination of the orbit has largely diminished.

THE PLANET JUPITER.—Jupiter's red spot, although preserving its oval form, is very dim, and is less sharp than in preceding years. The general aspect of the disc seems to have sensibly undergone changes and shows many more details, as if the cloudy atmosphere of the planet had been more than usual disturbed. Numerous observers are now scanning his disc, and some recent results are contained in the current number of *L'Astronomie* (No. 11). M. Guiot has made a series of drawings which are there produced; they show how the equatorial belt has gradually advanced to the west relatively to a small black spot indicated in the drawing, and has consequently made the latter appear to have a motion in the opposite direction, *i.e.* eastwards. The motion is clearly shown by a change of inclination in a line connecting the same two spots in the series.

A NEW VARIABLE STAR.—The Rev. T. E. Espin announces from the Wolsingham Observatory that a red star (anonymous) at R.A. 19h. 7m. 16s., Decl. +25°·46, is variable. Its magnitude on August 21 was 9·0, but it has diminished to 11·0 mag. Photographs taken with the Compton telescope have confirmed the variability of Es. 329 (R.A. 19h. 59m. 6s., Decl. +36°·25).

THE "OBSERVATORY" FOR NOVEMBER.—In the current number of this monthly, Mr. T. Lewis concludes his interesting survey on the various methods of computing double-star orbits. Mr. H. H. Turner describes briefly a short method of obtaining a star's right ascension and declination from a photograph, the results being correct to less than a second of arc. Mr. Dunkin, in a letter to the editors, gives the text of the "Adams Memorial," lately placed in the north transept of Truro Cathedral, and erected at the expense of a few Cornish friends and admirers, both resident and non-resident, as a mark of their high esteem for him as an astronomer and mathematician, and also for the strong affection he always entertained to the end of his life for the hills and dales of his native county. The translation is as follows:—

In this place, as is his due,
We commemorate our own [West] countryman
John Couch Adams
Tracing his way
By the sure clue of Mathematics
Through the boundless night of space
He found the outermost of the planets.
Faithfully pursuing the paths of the Sciences
With single-hearted modesty and clearness of intellect,
He loved God Whom he saw in the Face of Christ;
For him, as well as for Henry Martyn,
Cornwall and Cambridge
Owe each other mutual debts.
He died, dearly loved by all who knew him,
On the 21st of January 1892,
Aged 72 years, 7 months, 16 days.

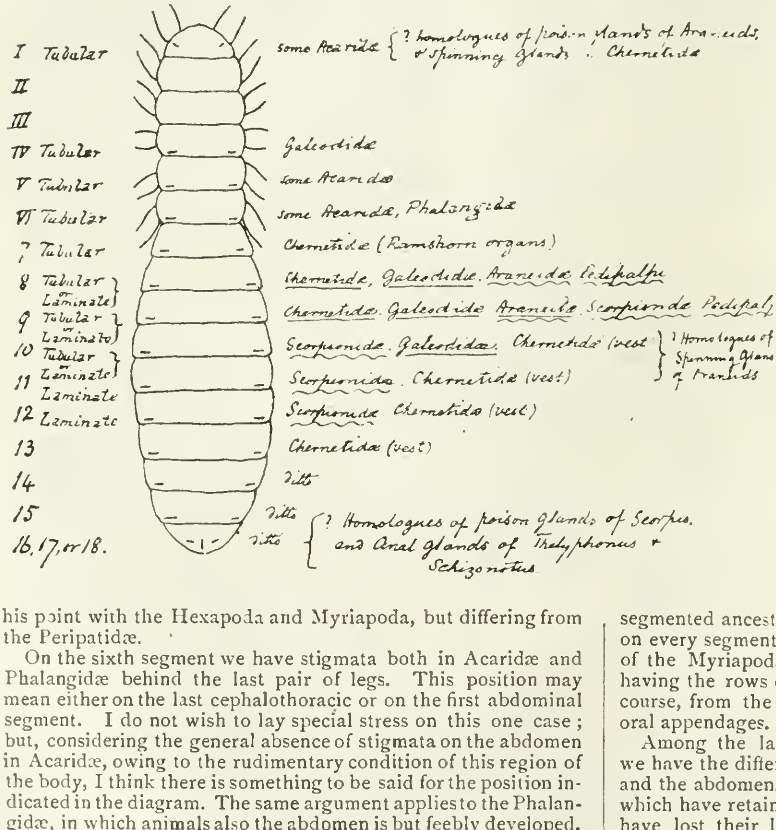
SOLAR OBSERVATIONS AT CATANIA, ROME, &c.—Prof. Riccò, in the August number of the *Memoire della Societa degli Spectroscopisti Italiani*, gives a detailed account of the observations of solar protuberances observed at the Royal Observatory of Catania during the year 1892. The same number contains two of the large diagrams showing the sun's limb as observed at Catania, Palermo and Rome, one for February-March 1892, and the other for March-April of the same year.

THE STIGMATA OF THE ARACHNIDA, AS A CLUE TO THEIR ANCESTRY.

IF on a diagram of an Arachnidan body we mark every segment on which stigmata are said to occur, the result is somewhat remarkable.

The subjoined figure is such a diagram, and stigmata, functional or vestigial, are known on all the segments except the second and third. On the left hand of the diagram I have recorded the form which the tracheal invaginations from each pair of stigmata assume, *i.e.* whether they are tubular or laminate ; and on the right hand I have noted the genera in which the stigmata occur, with a straight underline if their tracheæ are tubular, and a wavy underline if their tracheæ are laminate. The marks which represent the stigmata are not intended to denote their real positions on the segments, but only to indicate their presence, although there is reason for thinking that they may well represent their primitive positions.

On the first segment we have stigmata recorded *on the dorsal surface at the bases of the mandibles* in some Acaridæ. This remarkable position may be in some way connected with the formation and dorsal arrangement of the "cephalic lobes,"[1] which accompanies the translocation of the mandibles from a post-oral to a pre-oral position. All the other tracheæ of the Arachnida are associated with limbs, the Arachnida agreeing in



his point with the Hexapoda and Myriapoda, but differing from the Peripatidæ.

On the sixth segment we have stigmata both in Acaridæ and Phalangidæ behind the last pair of legs. This position may mean either on the last cephalothoracic or on the first abdominal segment. I do not wish to lay special stress on this one case ; but, considering the general absence of stigmata on the abdomen in Acaridæ, owing to the rudimentary condition of this region of the body, I think there is something to be said for the position indicated in the diagram. The same argument applies to the Phalangidæ, in which animals also the abdomen is but feebly developed.

On the first abdominal segment (7) we have the remarkable ram's-horn organs which I have elsewhere[2] suggested may be a primitive form of tracheal invagination, from which either laminate or tubular tracheæ may be very easily deduced.

On the following two abdominal segments (8 and 9) we have tubular and laminate tracheæ equally distributed, all those hitherto described having been tubular.

On the tenth segment we have functional laminate tracheæ in Scorpio, tubular tracheæ descending to a medium (? closed) stigma in Galeodes, and vestigial stigmatic scars in the Chernetidæ. These scars are repeated segmentally on all the remaining abdominal segments in the Chernetidæ, and represent the closed stigmata of vanished tracheæ, which tracheæ, if we may judge from the ram's-horn organs and the functional tracheæ on the second and third abdominal segments, were all most certainly tubular.

From these facts we are justified in concluding (1) that the tracheal invaginations of the ancestor of the Arachnids were strictly segmental, and (2) that these invaginations were of some simple tubular type, from which the laminate forms could be easily developed. The ram's-horn organs of the Chernetidæ, with the simple air chambers in their epithelial cells as recently described (*l.c. supra*), might well represent such primitive invaginations.

An impartial review of the facts must convince everyone that the laminate form is the more specialised. The tubular form is by far the most widely distributed, being not only universal among the Hexapoda and Peripatidæ, but far more common among Arachnids than the laminate. Tubular tracheæ occur universally in the Acaridæ, which have some claim to be considered as fixed larval forms (*Journ. Linn. Soc. Zool.* vol. xxiv. p. 279) ; in the Phalangidæ, which are so specialised that they must have branched off very early from the main Arachnidan stem ; in the Chernetidæ, which again are very difficult to class, and may claim to be an independent group ; and lastly in the Galeodidæ, which in many respects are the most primitive of all Arachnids.

The Araneidæ, with their highly specialised abdomen, possess both laminate and tubular forms, while the Scorpionidæ and related Pedipalpi are the only Arachnids, and indeed the only Arthropods (except a few Myriapods), which have exclusively laminate tracheæ. The laminate tracheæ of the Myriapods cannot possibly be deduced from the laminate tracheæ of the Arachnids, but both forms of laminate tracheæ can be deduced from a primitive tubular organ.

Returning to the diagram, the facts therein epitomised presuppose the existence in the ancestor of the group of simple limbs on every segment. In addition to the six pairs of limbs on the first six segments, clear traces of limbs are well known either in a persistent or a vestigial disappearing form on the first six abdominal segments. Further, we can conclude from the stigmatic scars on the Chernetidæ, that there must originally have been limbs on all the remaining segments of the abdomen. The character of these limbs may perhaps be gathered from those of the nymphs of many Acaridæ, which probably represent the earliest developmental stages in the Arachnida now traceable, and perhaps also from the legs of the Silurian Scorpion, *Palæophonus nuncius.*

We can thus trace the Arachnids back to a segmented ancestor with a pair of limbs and a pair of tracheæ on every segment—*i.e.* to an ancestral form resembling those of the Myriapoda and Hexapoda, but differing from these in having the rows of stigmata ventral instead of lateral, apart, of course, from the profound difference in the specialisation of the oral appendages.

Among the later modifications of this primitive Arachnid we have the differentiation of the body into the cephalothorax and the abdomen. The former consists of the first six segments which have retained their limbs. The segments of the latter have lost their limbs almost completely, rudiments, however, persisting as genital opercula, pectines, and spinning mammillæ. In the former the great development of limbs and musculature and the fusing of the segments together has led to a general suppression of the tracheal invaginations. One pair, however, persists in the Galeodidæ, *which, with the exception of Schizonotus, are alone among Arachnids in retaining the original jointing of the posterior cephalothoracic segments,* and in the Acaridæ and Phalangidæ, in both of which the abdominal region is not fully developed.

The second and third segments appear to be the only ones on which hitherto no traces of stigmata have been found. This may be due to the fact that in the formation of the mouth parts the first three segments early fused together.

The general disappearance of tracheæ from the cephalothorax

[1] "The 'Head' of Galeodes," &c. *Zool. Anz.* No. 426, 1893.
[2] "Notes on the Chernetidæ." *Linnean Society's Journ.* (in press).

necessarily confined the respiratory organs to the abdominal region. Further, those on the anterior segments of the abdomen would be gradually preferred for specialisation, as being nearer to the cephalothoracic musculature, and to the shelter of the limbs for the protection of the open stigmata. The Scorpionidæ alone, having highly developed musculature in the posterior abdominal segments, have the respiratory invaginations nearly evenly distributed along the middle of the abdominal region.

On the diagram I have further indicated a few suggested homologies. I have elsewhere[1] brought forward evidence in favour of the derivation of tracheæ from setiparous glands. The derivation of poison and spinning glands from similar structures is generally admitted. The consequent homology between the spinning glands and tracheæ requires a slight modification. When, as in the Hexapoda, most Myriapoda, and the Arachnida, the tracheæ are strictly segmental, and intimately associated with limbs, they have probably arisen from the large bristle sacs which secreted the specialised parapodial acicula; spinning glands, on the other hand, are more generally to be deduced from groups of ordinary bristle sacs, although they may also be deduced from acicular glands as well. It is important to bear this qualification in mind, as it helps to throw light on a difficult point in the morphology of the Araneids. While the two pairs of spinning glands on the two pairs of mammillæ are referable to setiparous glands on rudimentary limbs, and probably homologous with tracheæ, there are also, in the majority of spiders, median spinning glands between the mammillæ, which cannot be brought into connection with any rudimentary limbs. This difficulty is, however, fully explained by the position of the abdominal cement glands in the Chernetidæ, which serve to stick the eggs to the abdominal surface, in which position they are carried about by the parent. In these animals we have, on the second and third abdominal segments, median glands (originally paired) occurring *between* the two pairs of tracheal invaginations. In this case I should refer the tracheæ to acicular glands, and the cement glands on the same segment to groups of setiparous glands lying ventrally to the acicula. In the genus Galeodes, rows of short powerful bristles actually occur in the corresponding position, *i.e.* close to the median line on the second and third abdominal segments, and form the stigmatic combs, which are quite distinct from the stigmata themselves. According to this derivation we might have two pairs of spinning glands on each segment, one pair placed laterally on mammillæ, and one pair close to the median line between the mammillæ. This arrangement is actually found in the rare spider Liphistius, which has four pairs of spinning glands arranged as here described. This is especially interesting, because in addition to other primitive features Liphistius is alone among known spiders in retaining at least nine distinct abdominal tergites.[2]

The facts and suggestions here briefly set forward are a small instalment of the results obtained during my researches on the comparative morphology of the Galeodidæ, which I hope shortly to have ready for publication. I may, perhaps, add that the net results of these investigations go far to establish that classification which ranks the Arachnids as an independent group of the tracheate Arthrpodos, as distinguished from that which would deduce them from the specialised Crustacean Limulus through the specialised Arachnid Scorpio.

THE PRESENT STANDPOINT OF GEOGRAPHY.

Mr. Clements R. Markham, C.B., F.R.S. inaugurated the evening meetings of the new session of the Royal Geographical Society, on Monday night, by a presidential address on the present standpoint of geography. He gave a survey of the state of our actual knowledge of the earth's surface, and pointed out the regions where exploration may still be done. Viewing exact delineation by trignometrical measurement as the crowning work of geography, he pointed out how incomplete the exact mapping of the land surface of the globe still was, while the delineation of the bed of the ocean had hardly been begun. In the Polar regions, of course, lay the greatest unknown areas, and the two expeditions now in the field, Nansen's and Peary's, were referred to with some confidence as to their probable success. Mr. Markham himself believed that land exists between Prince Patrick Island and Siberia, which ought to be discovered, and was inclined to accept Lieut. Hovgaard's theory of extensive land north of Cape Chelyuskin. He indicated the delineation of the north coast of Franz Josef Land as one of the more important pieces of Arctic work for the near future. Consideration of the vast Antarctic field was postponed until Dr. Murray's paper at the next meeting.

In Europe there remained scope for detailed survey in many countries, and Mr. W. H. Cozens-Hardy's recent labours on the frontiers of Montenegro are only a foretaste of what has to be done in the Balkan Peninsula. The Cantabrian mountains on the west, and the Caucasus on the east, contain still many isolated unknown patches.

In Africa the unknown had been diminishing within his memory more rapidly than anywhere else, and the days of suddenly-planned expeditions discovering features of the first magnitude had altogether passed. What remain unknown are two great areas in the Sahara, in the Tibesti, and Ahaggar highlands, the negro kingdom of Wadai, and the region stretching from Southern Abyssinia into the Somali Peninsula. In countless places detailed work has to be done, such as Dr. Gregory's study of Mount Kenia, and Mr. Scott-Elliot's similar detailed survey of the Ruwenzori region, just undertaken. The best future work for geography in Africa lies in surveying rather than exploring, and lines of survey should be run across the continent in defined and well-thought-out directions.

Asia has also new ground to break into. The valleys of Hadramant, in Arabia, are almost as little known as the Antarctic regions, and Mr. and Mrs. Bent will shortly endeavour to explore that district. In Asia Minor and Persia much detailed surveying must be done. In Central Asia there is Lhassa, unvisited by an Englishman for generations, and a vast region in north-western Tibet, between 34° and 36° N., and 82° and 90° E. is a blank upon our maps, in spite of the magnificent journeys recently made by Bower, Rockhill, and the Russian explorers. Nearer India, Nepal is little known; Kafiristan is absolutely secluded from the European, and there could be no nobler ambition for a young geographer than to be the first to explore Kafiristan. The maze of mountain ranges and river valleys east of the Himalayas has yet to be unravelled, and the whole interior of Indo-China is full of opportunities for research. Korea, in the far east, is yet far from being fully known. The great Malay Archipelago must receive much more attention, and the problems of western New Guinea alone, with the grand range of the Charles Louis mountains, are well worthy of being seriously attacked. Upraised coral atolls in the Solomon Islands have been reported but not visited. As regards new discovery, however, there is probably no undiscovered islet remaining in the whole Pacific.

Australia, except some desert patches in the west, has been practically explored, although immense areas have still to be surveyed, and the development of colonial geographical societies gives good promise of that continent being thoroughly studied from within.

In North America, Dr. George Dawson enumerates a number of great stretches of land, aggregating several hundred thousand square miles, absolutely untraversed by any intelligent white man. These lie mainly north of the Arctic circle, between the great rivers that flow into the Arctic Sea and in Labrador. Alaska also has its unknown tracts, and even in the United States there is much room for detailed surveys.

Central America is not well known, and in South America much of the Colombian Andes, the basins of the Japura and Putumayo, the whole tract between the Andes and the Orinoco and Rio Negro, are practically unknown. In Peru whole provinces are unexplored, and many peaks unmeasured.

Oceanography is only beginning to yield results, and other departments of generalised physical geography are of growing importance. The better instruction of intending travellers, inaugurated by the Society, and carried out by Mr. Coles, has done much to confer value on the observations of officials, traders, and missionaries, while the more thorough study of theoretical geography, now beginning, requires great extension and elaboration before its work would be thorough.

SOME LABORATORIES OF MARINE BIOLOGY.

THE description of some of the Marine Biological Laboratories of Europe, contributed by Mr. Bashford Dean to the *American Naturalist* for July, and reprinted in NATURE, August 24, was continued by the author in the August number of our transatlantic contemporary. Some of the most important laboratories were omitted in the first article. but they are included in the second, from which the following account has been taken :—

"The Stazione Zoologica at Naples during the past twenty years has earned its reputation as the céntre of marine biological work. Its success has been aided by the richness of the fauna of the Gulf, but it is due in no small degree to careful and energetic administration. The director of the station, Prof. Dohrn, deserves no little gratitude from every worker in science for his untiring efforts in securing its foundation and systematic management. Partly by his private generosity and partly by the financial support he obtained, the original or eastern building was constructed. Its annual maintenance was next assured by the aid he secured throughout (mainly) Germany and Austria. By the leasing of work tables to be used by representatives of the universities, a sufficient income was maintained to carry on the work of the station most efficiently. A gift by the German government of a small steam launch added not a little to the collecting facilities."

After commenting upon the attractiveness of the Naples station, and the general air of quietness which results from the excellent system that prevails in every branch of the station's organisation, Mr. Dean goes on to describe the aquarium room, which is lighted only through wall-tanks. "There are in all about two dozen large aquaria embedded in the walls of the sides and of the main partition of the room. The water is clear and blue. The background in each aquaria, built of rockwork, catches the light from above and throws in clear relief the living inmates."

"There is no more interesting department of the station than that of receiving and distributing the material. . . . Neapolitan fishermen have learned to bring all of their rarities to the station. The specimens are quickly assorted by the attendants ; such as may not be needed for the immediate use of the investigators are retained and prepared for shipment to the universities throughout Europe. The methods of killing and preserving marine forms have been made a most careful study by Cav. Lo Bianco, and his preparations have gained him a world-wide reputation. Delicate jelly-fish have to be preserved distended, and the frail forms of almost every group have been successfully fixed. The methods of the Naples station were kept secret only until it was possible to verify and improve them, as it was not deemed desirable to have them given out in a scattered way by a number of investigators."

There are at present two American tables at Naples, one supported by the Smithsonian Institution, and the other by gift of Agassiz.

"The entire Italian coast is so rich in its fauna that it is due perhaps, only to the greatness of Naples, that so few stations have been founded. Messina has its interesting laboratory well known in the work of its director, Prof. Kleinenberg. The Adriatic, especially favourable for collecting, has at Istria a small station on the Dalmatian coast, and at Trieste is the Austrian station. Trieste possesses one of the oldest and most honoured of marine observatories, although its station is but small in comparison with that of Naples, Plymouth, or Roscoff. Its work has in no small way been limited by scanty income ; it has offered the investigator fewer advantages, and has, therefore, become outrivalled. During a greater part of the year it is but little more than the supply station of the University of Vienna, providing fresh material for the students of Prof. Claus. Its percentage of foreign investigators appears small ; its visitors are usually from Vienna and of its university."

Dr. Graeffe is the director of this station. With regard to laboratories of marine biology in Germany, Norway, and Russia, Mr. Dean says :—

"The German universities have contributed to such a degree to the building up of the station at Naples that they have hitherto been little able to avail themselves of the more convenient but less favourable region of German coasts. The collecting resources of the North Sea and of the Baltic have perhaps been not sufficiently rich to warrant the establishment of a central station. On the side of the Baltic, the University of Kiel, directly on the coast, may itself be regarded a marine station. At present the interest in founding local laboratories has, however, become stronger. At Plön, not far from Flensburg, is established a small station under the directorship of Prof. Zacharias, and the first number of its contributions has recently been published. In addition the newly-acquired Heligoland has become the seat of a well-equipped Governmental station, under the directorship of Dr. R. Heincke. The island has been long known as most favourable in collecting regions, and its position in the midst of the North Sea fisheries gives it especial importance.

"Norway, like Germany, is strengthening its interest in local marine laboratories. It has succeeded in establishing two permanent stations, one near Bergen, the other, most recently, on an out-jutting point of the North Sea almost westward of Christiana. The former is interested especially in matters relating to the North Sea fisheries, and is supported partly by the contributions of a learned society and partly by a subsidy from the Government in view of its relation to the practical fisheries. The second and smaller station is devoted almost exclusively to research in morphology. It is a dependency of the University of Christiana, and is under the directorship of one of its professors, Dr. Johan Hjört. With the richest collecting resources these new stations may naturally be expected to yield most important results.

"Russians have ever been most enthusiastic in marine research, and their investigators are to be found in nearly every marine station of Europe. The French laboratory on the Mediterranean at Ville Franche, as has previously been noted, is supported essentially by Russians. At Naples they are often next in numbers to the Germans and Austrians. The learned societies of Moscow and St. Petersburg have contributed in no little way to marine research. The station at Sebastopol on the Black Sea has become permanent, possessing an assured income. That near the convent Solovetsky on the White Sea, though small, is of marked importance. It is already in its thirteenth year. Prof. Wagner, of St. Petersburg, has been its most earnest promoter as well as constant visitor. He in fact caused the Superior of the convent to become interested in its work and secured a permanent building by the convent's grant ; he was then enabled by an appropriation from Government to provide an equipment. Its annual maintenance is due to the Society of Naturalists of St. Petersburg. The matter of the appointment of a permanent director for the summer months is now being agitated. The station Solovetskaia is said to possess the richest collecting region of the Russian coasts. It is certainly the only laboratory which has at its command a truly Arctic fauna."

The article concludes with a brief description of the Swedish zoological station on the west coast near Gothenberg. The station was founded by Dr. Regnell about fifteen years ago, and Dr. Hjalmar Theel is its present director. The students are mainly from the university of Upsala ; indeed, no foreigners are admitted to it.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The accommodation for students in the Radcliffe Library has been improved by the removal of the sub-librarian's office to the room under the central tower and the provision of several new reading tables in the space thus created. But as the numbers of scientific students continue to increase, it is clear that some more extensive and permanent addition will very soon be necessary. The number of regular readers in the library this term is seventy-nine ; ten years ago it was only thirty-one, and in the previous decade it was seldom that more than five or six students made use of the library in a single day. These figures give some idea of the gradual growth of scientific studies in the University. A proposal has been set on foot, which, if it is carried out, is likely to affect scientific studies in Oxford very beneficially. It is, that besides the existing means of obtaining a degree by examination, facilities shall be given for obtaining a degree for research in any recognised subject. It is proposed that a residential qualification of two years shall be imposed on any candidate for such a degree, and that evidence must be brought forward of continuous research and study, to the satisfaction of the board appointed for the purpose. At

present the scheme has merely been brought before the Hebdomadal Council, and has, as yet, assumed no definite shape.

CAMBRIDGE.—The Local Examinations and Lecture Syndicate have presented to the Senate their twentieth annual report. The most important event of the year has been the establishment of the University Extension and Technical College at Exeter. The college has been established by the co-operation of the Town Council of Exeter, the University Extension Committee of Exeter, and the Syndicate, and Mr. A. W. Clayden, of Christ's College, has been appointed principal. The work done for County Councils under the authority of the Syndicate has been continued during the past year. There has been a considerable diminution in the area covered, as County Councils have been able to utilise to a greater extent than before the services of local teachers, and have spent a larger proportion of their available funds in grants in aid of permanent institutions for technical teaching. On the other hand, the reports received from lecturers indicate considerable improvement in the quality of the work done. About 650 students attended the summer meeting, of whom 150 were men and 500 women. On the whole the work done was satisfactory, though a certain number of students attempted too many subjects. It is not considered desirable to hold such meetings oftener than once in two years, but classes on a smaller scale may satisfactorily be held in the alternate long vacations. From Mr. Arthur Berry's report to the Syndicate it appears that the stimulus given to the work of the local lectures last year by the activity of the County Councils in the matter of technical education has lost a good deal of its effect, as more permanent institutions for educational purposes are gradually being organised. Not only have literature and history thus suffered, but courses on branches of science not of obviously practical utility (such as astronomy) have tended to be displaced by more "technical" subjects. It is satisfactory to learn that such engagements as have already been made for the ensuing winter indicate a distinct reaction against the exclusive study of "bread and cheese" subjects.

In resigning office on September 30, the late Vice-Chancellor, Dr. Peile, called attention to the lack of funds for research in several of the scientific departments. He is now able to announce that an anonymous member of the Senate has placed in his hands £100 for the support of higher work in the Pathological Department during the coming academical year.

A fire, which took place at the Pitt Press last week, has necessitated the temporary evacuation of the room occupied by the Registrar. The Old Library of Pembroke College has been placed at his disposal by the Master and Fellows, and the business of the office will be carried on there during the present term.

The scheme for examinations in agricultural science under a managing syndicate was non-placeted on November 9, but was carried by a very large majority. The proposal to postpone the conferring of Honours degrees to the Long Vacation, in order to give more time for the Tripos examinations, was rejected.

The *University Reporter* of November 14 contains notices of scholarships in Natural Science open for competition to non-residents at Peterhouse, Clare, Pembroke, King's Queen's, St. John's, and Sidney Sussex. The examinations will be held in December and January next.

TRINITY COLLEGE, DUBLIN.—There is during this term a large increase in the number of students interested in the study of biology; so large, in fact, that the accommodation in the Botanical Laboratory has had to be increased. This is a pleasing feature in a university so long devoted to classical pursuits.

At the recent Moderatorship Examinations, three candidates, C. J. Patten, F. K. Boyd, and N. H. Alcock, obtained Senior Moderatorships, and were awarded gold medals in Natural Science (Botany, Zoology, Geology, and Physiology). During the week the University Experimental Science Association held its opening meeting, when a very large audience assembled to hear Dr. Joly, F.R.S., deliver a lecture on "Some Applications of Photography." The Provost, Dr. Salmon, occupied the chair.

THE *British Medical Journal* says that steps are being taken to arrange for a deputation representing the university colleges in England to wait, shortly, upon the Chancellor of the Exchequer, to urge upon him the propriety of increasing the annual parliamentary grant. A sum of £15,000 has been granted annually since 1890, and when this sum was first placed upon the estimates, it was understood that the question would be reviewed at the end of five years. A Treasury Committee, consisting of Sir Henry Roscoe, Mr. George Curzon, Prof. Bryce, Mr. R. G. C. Mowbray, and Mr. W. J. Courthope, have reported recently in favour of the grant being doubled, pointing out that all educational work connected with science is increasing yearly in cost, and that the growth in the number of students and the enlargement of the teaching staff have contributed to strain the resources of the colleges.

SCIENTIFIC SERIALS.

Bulletin of the New York Mathematical Society, vol. iii. No. 1. (New York: Macmillan, October, 1893.)—A congress of mathematics and astronomy was opened at Chicago on August 21, and this number commences with Dr. Felix Klein's inaugural address. It is brief but not witty, and merely sketches some of the papers to be read, and closes with the remark that mathematicians must go farther than to form "mathematical societies." "They must form international unions, and I trust that this present congress at Chicago will be a step in that direction." Prof. T. H. Safford narrates briefly, in his remarks on "instruction in mathematics in the United States," the history of the noteworthy rise in the general standard of mathematical teaching within the last few years. Prof. Ellery Davis reviews four recent geometries, viz. those by Hopkins, Dupuis, W. B. Smith, and Halsted. Prof. Tyler analyses the papers read at the Chicago congress, and Prof. Waldo gives a brief account of the American Association meeting at Madison on August 16-23. Three pages of notes of mathematical doings, and eight pages of new publications follow. This last feature of the *Bulletin* is a very prominent and highly valuable one.

THE *American Meteorological Journal* for November contains an account of the second annual meeting of the American Association of State Weather Services, held in Chicago, on August 21-23, 1893. The meeting was well attended, and resolutions were adopted on various subjects, among which may be mentioned the issue of weekly crop bulletins. It was also recommended that the bottom of thermometer screens should be four and a half feet above the ground; this would make the thermometers about a foot higher than is recommended in this country. It is stated that experiments made during the past year prove the former elevation to give the best results.—Mr. C. E. Linney read a paper on the value of frost predictions, and the best method of making them locally. The author is of opinion that with a knowledge of the ordinary weather signs an observer can, by the aid of the wet and dry bulb thermometers, form a good idea of what minimum temperature to expect during the night.

IN the *Transactions of the Austrian Geological Survey* we remark an important communication, made by Mr. Friedrich Teller, "On the so-called Granite of the Bacher Mountains in South Steiermark." It seems that the familiar term, "granite of the Bacher," has been entirely misapplied. In the eastern part of these mountains the rock is granitic *gneiss*, forming a dome-shaped core beneath the crystalline schists; while the so-called granite in the western part is an intrusive *porphyrite*, younger than the whole series of schists and phyllites, and possibly of the same age as the porphyrite which penetrates Triassic and Jurassic strata in the neighbouring district.—Dr. A. Kornhuber gives the name of *Carsosaurus Marchesetti* to a new Saurian genus from the Karst district. It was found in the same cretaceous shales as Acteosaurus, a genus described thirty years ago by Hermann Meyer, and was erroneously thought to be merely a larger specimen of Meyer's genus.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, November 6.—M. Lœwy in the chair.—On Goubet's joint and its application to marine screw-propellers, by M. H. Resal. This is a mathematical investigation of the action of a joint capable of making the propeller act as supplementary steering gear, and of adapting it to submarine navigation. It is shown to possess several advantages over the

similar American Clemens joint.—On a class of differential equations whose general integral is uniform, by M. Emile Picard.—Significance of the variety of organs in the gradation of vegetable species, by M. Ad. Chatin.—On a Nymphæa bed recently found and explored in the Aquitanian of Manosque, by M. G. de Saporta.—On equations of the second order with fixed critical points, and univocal correspondence between two surfaces, by M. Paul Painlevé.—On certain ordinary differential equations, by M. Alfred Guldberg.—On certain families of gauche cubes, by M. Lelieuvre.—On the nature of the reflection of electric waves at the end of a conducting wire, by MM. Kr. Birkeland and Ed. Sarasin.—Observations upon the preceding communication of MM. Birkeland and Sarasin, by M. H. Poincaré. This is an application of Maxwell's theory to the phenomena of propagation of energy into space round the end of a conducting wire along which electric waves are passing. It is shown that the deductions from the theory are in general accord with the facts observed.—On the measurement of co-efficients of induction, by M. H. Abraham. The employment of a differential galvanometer in these measurements permits of an accurate determination within 1 per cent., and a reading to within 0·1 per cent. without much difficulty. The induced currents from a commutator regulated by a stroboscopic method are sent through one circuit of a differential galvanometer, the deflection being compensated by a continuous current derived from the same battery. The commutator is then stopped, and a current equivalent to the induced current is derived from the primary circuit through a resistance r, and sent through the secondary circuit, r being chosen so as to establish equilibrium in the differential galvanometer. Then this actual resistance r may be put equal to the fictitious resistance nM obtaining while induction was going on, and we have $M = \frac{r}{n}$ where M is the co-efficient of mutual induction, and n the frequency of the commutator. The resistance r may be constituted by a standard ohm coil. M. Abraham has found by this method that the coefficient of mutual induction is reciprocal in the case of two circuits free from iron, but that this reciprocity is disturbed if they contain iron cores.—On vision of opaque objects by means of diffracted light, by M. Gouy. If an opaque and non-reflecting object is examined by means of a microscope or telescope, the object being placed in the path of a beam of light, the image is formed both by the rays following geometrical paths and by those diffracted by the outlines of the object. If the former are intercepted, the diffracted rays only form the image. This may be done by placing a small screen at the focus of the object-glass inside the telescope, so as to intercept the rays from a very distant source which converge there. The outline of the object is then seen as a thin bright line on a dark background, and with sufficient enlarging power this line is seen to consist of two, very close together, and separated by a very sharp black line. This black interval disappears on intercepting the diffracted rays either inside or outside the geometrical shadow, thus showing that it is due to the interference of these two beams. They possess a difference of phase of half a wave-length, and equal amplitudes. An arrangement such as this may prove useful when the outlines of an object require to be sharply defined.—On a new method of preparing methylamine and on the constitution of hexamethylene-tetramine, by MM. A. Trillat and Fayollat.—On the alkaline methyl-tartrates and ethyl-tartrates, by M. J. Fayollat.—Researches on the homologues of gallanilide; preparation of galloparatoluide, by M. P. Cazeneuve.—Experimental hereditary influences, by MM. Gley and Charrin.—On a phenomenon of inhibition in Cephalopoda; paralytic constriction of chromatophores, by M. C. Phisalix.—On the serial craniological continuity in the genus Lepus, by M. Remy Saint-Loup.—On the genus *Polydora* Bosc (*Leucodore* Johnston), by M. F. Mesnil.—The *Callibrachion*, a new reptile of the Permian of Autun, by MM. M. Boule and Ph. Glangeau.—On the glacial and erratic phenomena in the Cachapoal Valley (Andes of Chili), by M. A. F. Noguès. The phenomena of transport by water and glaciers have contributed to the formation of the erratic system in the valleys of the Chili Andes. There must have existed lakes or deep terrace ponds. The glaciers must formerly have descended further than they do at present, and at the Cachapoal they are actually retreating now.—An earthquake shock at Grenoble, by M. Kilian. This happened at 4h. 13m. 40s. A.M., Paris time, on November 5, in a direction from N. to S., and was recorded by the seismometer of the Geological Laboratory of the Faculty of Sciences.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Social England: edited by H. D. Traill, vol. i. (Cassell).—New Technical Educator, vol. ii. (Cassell).—Guelphs and Ghibellines: O. Browning (Methuen).—Intensity Coils, 18th edition (Perken). The Magic Lantern, 2nd edition (Perken).—British Fungus Flora: G. Massee, vol. 3 (Bell).—Weather Lore: compiled, &c., by R. Inwards (Stock).—Les Courants Polyphases: J. Rodet et Busquet (Paris, Gauthier-Villars).—Pour Devenir Financier: R. Chevrot (Paris, Gauthier-Villars).—Golf: a Royal and Ancient Game: edited by R. WATSON'S KINETIC THEORY OF GASES.

A Treatise on the Kinetic Theory of Gases. By Henry William Watson, D.Sc., F.R.S. Second Edition. (Oxford: at the Clarendon Press, 1893.)

THE rather pointed reference to myself, which Dr. Watson makes at the end of this new edition of his work, seems to call for an answer. Had this call come some five or six years ago, when the questions once again at issue were debated in a somewhat lively way, I should have had little difficulty in rising to it:—but I have in the interval been so busy with questions of a totally different nature that I am taken at a disadvantage, especially as I cannot at present find time to read up again the discussions of that period. I remember enough about them, however, to make the very positive assertion that the questions then raised turned on points of logic, relevancy, and consistency, much more than upon physical ideas or mathematical processes; and a perusal of Dr. Watson's volume shows me that he has reproduced from Boltzmann and others much of what I then objected to. I believe that I gave, in 1886 (*Trans.* R.S.E. vol. xxxiii.), the first (and possibly even now the sole) thoroughly legitimate, and at least approximately complete, demonstration of what is known as Clerk-Maxwell's Theorem, relating to the ultimate partition of energy between or among two or more sets of hard, smooth, and perfectly elastic spherical particles. And I then pointed out, in considerable detail, the logical deficiencies or contradictions which vitiated Maxwell's own proof of 1859, as well as those involved in the mode of demonstration which he subsequently adopted from Boltzmann. Dr. Boltzmann entered, at the time, on an elaborate defence of his position; but he did not, in my opinion, satisfactorily dispose of the objections I had raised. Of course I am fully aware how very much easier it is for one to discover flaws in another man's logic than in his own, and how unprepared he usually is to acknowledge his own defects of logic even when they are pointed out to him. But the only attacks which, so far as I know, have been made on my investigation, were easily shown to be due to misconception of some of the terms or processes employed.

Dr. Watson's little work has been for many years the recognized text-book on the kinetic theory of gases:—and there can be no doubt that, considered in the fierce light of the Examination Hall, it is well adapted to the wants alike of actual Moderators and of would-be Wranglers. It is so framed as to be easily dissected into compact and thoroughly self-contained pieces of book-work:—from "easy" up to "rather stiff":—and, were these to be answered at all nearly in the words and formulæ of the text, few Examiners would venture to refuse full marks. From this point of view nothing more could be desired; for incorrect historical notices, such as the ascription of the origin of the theory to J. Bernouilli (properly D. Bernoulli) instead of R. Hooke, will injure no man's place in the Tripos. The purely mathematical part, mainly a series of exercises in the transformation (by functional determinants) of differential elements from one system of variables to another, though elegant enough, presents an aspect of sameness. *Toujours perdrix!* To this point we will recur.

Considered as a scientific treatise, however, and as practically the only one in Britain which deals at all fully with the subject, the work is not quite so deserving of commendation. Much of course has, in all cases, to be allowed for the almost necessary defects of a book which deals in any way with questions of probability. It has been the good fortune of but a very few, even among the most gifted of mathematicians, to be able to thread their way in safety through the countless traps and pitfalls which lurk unnoticed, often undiscoverable till they have done their worst, in every part of every region of this fascinating domain:—not, as in other subjects, in the partially explored nooks and crannies alone. But probability is only one application of logic:—and, in the passages we most object to, it is in general ordinary logic which we think is somewhat lightly treated. We do not require to go far in search of an example.

At the very commencement of the work, while dealing with Maxwell's well-known result for the permanent distribution of velocities among a number of equal, smooth, spherical particles, Dr. Watson says:—

"We assume that in the permanent state the distribution of the spheres throughout the space occupied by them is homogeneous in all respects; that is to say, on an average of any long time there are the same number of spheres in a given volume wherever that volume may be situated, and the law of distribution of velocities is the same throughout that volume as in the whole region under consideration."

On this statement we would remark that it is rather vague and incomplete:—for surely it is meant that the distribution is isotropic as well as homogeneous; and the word "long" has absolutely no meaning until the time-unit is assigned. Dr. Watson then proceeds to investigate the circumstances of an individual (but typical) collision. Here, however, logic steps in, and says:—"Halt! You have already *assumed* all that you need learn from collisions, so far at least as concerns the solution of the problem before you." In fact the assumption, read as above, leads at once to Maxwell's Law, by the very process which its discoverer first employed; a process depending on principles freely used throughout the text of this book. When Dr. Watson has found the state of motion (F), of two spheres after collision, in terms of the state (E) before it, he proceeds thus:—

"For permanence of distribution . . . it is sufficient that the number of collisions of pairs of spheres in state E during the time *dt* should be equal to the number of collisions of pairs in the state F during the same time."

This leads, of course, to Maxwell's result. But it is not hypercritical to ask whether the above-mentioned requirement is not merely "sufficient" but *much more than* sufficient:—so exacting, in fact, as to be absolutely unattainable. Note the consequences of it. From the very nature of the data, the whole motion in the present case is strictly *reversible*, so as exactly to retrace its entire history. But, if we were to reverse it, we should still have the "permanent" state:—*i.e.* one which could never have been otherwise than as it is! This principle of reversion underlies a great part of the theory; and a mere reference to it would, in many of the later pages of

the book usefully take the place of a multitude of imposing but superfluous symbols.

Another notable point in the investigation, to which attention should be drawn, is the mode of obtaining the expression for the probability of collision. This is given as proportional to the component of the relative speed along the line of centres at impact; and *not* to the relative speed itself, though this is *proved* to be the case in § 5. The final result, however, is rendered correct by means of a compensating error in the specification of the element of space really involved. This procedure cannot fail to bewilder a thoughtful reader.

All these remarks, it is to be observed, are made on the very first proposition in the work:—the "green tree," as it were! What might not be expected in the "dry"; *i.e.* the demonstration of Boltzmann's Theorem, to which the book gradually leads up? But I must not now recapitulate the objections which I made (about 1886-8) to Boltzmann's methods, nor the modes in which he defended them. Those who are curious about the matter may be referred to the *Phil. Mag.* for that period. All I need here say is that I do not think that Dr. Watson's book meets any of my objections.

From the experimental point of view, the first great objection to Boltzmann's Theorem is furnished by the measured specific heats of gases; and Dr. Watson's concluding paragraphs are devoted to an attempt to explain away the formidable apparent inconsistency between theory and experiment. In particular he refers to a little calculation, which I made in 1886 to show the grounds for our confidence in the elementary principles of the theory. This was subsequently verified by Natanson (*Wied. Ann* 1888) and Burbury (*Phil. Trans.* 1892). Its main feature is its pointing out the absolutely astounding rapidity with which the average amounts of energy per particle in each of two sets of spheres in a uniform mixture approach to equality in consequence of mutual impacts. Thus it placed in a very clear light the difficulty of accepting Boltzmann's Theorem, if the degrees of freedom of a complex molecule at all resemble those of an ordinary dynamical system. P. G. TAIT.

A HISTORY OF CRUSTACEA.

A History of Crustacea. Recent Malacostraca. By the Rev. Thomas R. R. Stebbing, M.A. With numerous illustrations. (The International Scientific Series, Vol. lxxiv.). (London: Kegan Paul, Trench, Trübner, and Co., Ltd., 1893.)

"THE ambition of this volume," writes the author in his preface, "is that it shall be one to which beginners in the subject will naturally have recourse, and one which experienced observers may willingly keep at hand for refreshment of the memory and ready reference." A most laudable ambition, and one that the author, we doubt not, set out with an intention to fulfil. The want of a volume of this very sort upon this subject had been often felt by both the student and the expert. The advance in our knowledge of the group had made it impossible to annotate effectively that model "History of the Crustacea," written by Milne Edwards, and Mr. Stebbing's painstaking, excellent memoir on the Amphipods of the *Challenger* Expedition had pointed him out as a possible author of a useful manual. To write, however, a useful manual or history requires that one should take a wide and all-sided view of the subject, so as to secure a fair symmetry in its treatment; once the amount of detail to be given has been determined upon it should be rigidly adhered to, and, needless almost to add, no useless or unnecessary matter should be allowed to obtrude itself. Therefore, to a knowledge of the subject there must be added certain powers of judgment, to which it would be well to join certain gifts of style, in order that a satisfactory result might be obtained.

None will deny to the author of this history of Crustacea a knowledge of his subject, and the immense amount of facts that he has condensed into the four hundred small pages of this volume will astonish those who peruse it. But for all this there is abundant evidence that it was begun without any sort of judicious calculation as to its scope, and the reader will be as sorry on the discovery as we fancy its author was, that the dire necessity of space has made what purports to be a history of the Crustacea into only a manual of the Malacostraca, and not even a complete manual of this sub-class, for at page 436 we read: "To complete the sketch of the Malacostraca, the sub-order of the Amphipoda *remains to be described.*" Chapters describing this sub-order had been written, when it appeared they overflowed the utmost space that could be allowed, and with this statement the "History of the Crustacea" ends. Our sympathies are with the author, for might we not have expected something excellent about a sub-order that he had made so peculiarly his own, and had we not a right to expect, after reading the first fifty pages, some information about the vast swarms of Entomostraca and Cirripedia. Apparently it was all ready, but the author was met with a "to so far you may print, and not a page further." The promises of what may be in the future seem too uncertain to depend upon.

Having thus expressed our disappointment about what we have not been given, we proceed to record our opinions as to what the publishers have allowed. The volume opens with an introduction of some fifty pages, which treats of the classification of the Crustacea in outline, giving us brief details of the sub-classes and orders, notes on the geographical distribution, hints as to collecting, statements about size and description of the segments and their appendages. This is followed by a table of the sub-classes, orders and sub-orders, and the account of the Malacostraca, as far as the end of the Isopoda. The plan adopted is to give a short diagnosis of the orders and sub-orders, the tribes and families; under these last, the principal genera and some of the more important species are given.

While dates are appended to the genera, and the names of the describers are given, yet there are only in two or three instances any indications as to where the descriptions are to be found. It would have added much to the value of the work had it been possible to have given these, but of course it would have added (whatever scheme was adopted) very greatly to the amount of the text. Possibly a little more information of this sort might have been squeezed in had the pen been struck through a number of useless sentences which rather

detract from the scientific aspect of the volume ; such as the statement of the views of the "very intelligent student" on the subject of the eyes of the shrimp (p. 225) ; the suggestion that the "Sea-devil" of the Mediterranean might well be the "great fish" referred to in the Book of Jonah (p. 222) ; the criticism on Spence Bate's description of *Parathanas immaturus*, apparently only given to afford the opportunity of quoting an ungallant saying about women (p. 233), and several such like ; or we could have been spared three pages about *Birgos latro*, or the half-page of a justification for giving Hansen's most excellent synoptic table of the Cymothoid group. Indeed, the author's desire not to make this manual a "dry and repulsive catalogue" has made him write a number of sentences which the seriously-minded reader will find it better to pass over with a very cursory eye. To conclude all we have to say on this aspect of the volume, we have strong objections to urge to the page headings, as being an attempt not to help but to confuse. Possibly the author may not be accountable for these ; they have often so little to do with the subject of the matter in the pages, that it is not unlikely that they were selected by some one as ignorant of the subject as of good taste ; as examples we quote the following : "The tail unique," "A box of branchiæ," "An affectionate squeeze," "Perils of baby-farming," "Looking like a buffoon," "How genera are generated," and many such like.

With all these little defects, which might so easily have been avoided, this volume will be indispensable to the student of this class of Arthropods ; it brings together in an intelligible form an immense mass of literature. In some of the orders most complete lists of genera and species are given, notably among the Isopods. Those species interesting either for their morphological, geographical, or bathymetrical distribution, are invariably mentioned, and so far as we can judge, all the British species are named. Most useful will this volume, compact in size and well-packed with information, be to collectors. There is at present no one work that can compete with it. Perhaps the day may come when our great National Museum may publish a revised list of all known Crustacea, as they have done of the fishes, reptiles, and birds ; till then Mr. Stebbing's volume will not lose its value, a value that would be greatly increased should a companion volume be published giving the history of the remainder of this interesting group. The work is embellished by nineteen plates and thirty-two illustrations in the text.

OUR BOOK SHELF.

An Elementary Treatise on the Geometry of Conics. By A. Mukhopadhyay. (London: Macmillan, 1893.)

THIS work is well adapted for junior students. It treats of the principal properties of the curves, and may well be read after a pupil has mastered his six books of Euclid. The starting point is from the focus and directrix definition, and no modern methods (as projections) are employed, nor are the curves shown to be obtainable from plane sections of the cone. Each curve has a chapter allotted to its discussion, which is conducted, as far as possible, on uniform lines. To the parabola are assigned twenty-five propositions, to the ellipse thirty-five propositions, and to the hyperbola thirty-seven propositions, with an additional five for the rectangular form. The order of treatment is mechanical description, chord properties, and then tangent properties. The proofs should be readily mastered by a boy who knows his Euclid, for they are clearly and simply put, and the author does not assume the truth of a converse proposition, as we have noticed some writers do. Mr. Mukhopadhyay has read far and wide in his subject, and has brought together in his 800 exercises a large collection of the most interesting problems. Many of these he accompanies with full solutions, and to very many more he furnishes suggestive hints. The figures are white on a black ground. The book appears to be very correctly printed ; at any rate, we have detected very few (easily corrected) misprints. The book appeals successfully to a larger public than the students of the Indian colleges.

The Geometrical Properties of the Sphere. (Univ. Corr. Coll. Tutorial Series.) By William Briggs and T. W. Edmondson. (London : W. B. Clive, 1893.)

IN these fifty pages the authors have brought together most of the chief geometrical properties of the sphere, intending the book to be used as a companion to their larger one, on mensuration of the simpler figures, by students preparing for the intermediate examinations in Arts and in Science of the University of London. The three chapters into which the subject is divided lead the reader from the elementary definitions relating to great and small circles, poles, lunes, &c., through the numerous geometrical properties of spherical triangles and their antipodal triangles, polar triangles, supplemental triangles, and finally to the determination of the area of lunes, spherical triangles, spherical polygons, and the spherical excess. The definitions and theorems are expressed quite clearly throughout, while the figures leave nothing to be desired. As an introduction to works on spherical trigonometry, students will find this book a most helpful guide. Two minor slips in construction will be found : one on page 6, line 6, where for CT read TC ; and the other on page 18, line 9, where for *oa* and *ob* read *ao* and *bo*.

A Key to Carroll's Geometry. By J. Carroll. (London : Burns and Oates, Ltd., 1893.)

THIS key contains the solutions of the exercises in orthographic projection and solid geometry, which are given in the author's book on geometry. The solutions seem to have been thoroughly and carefully worked out. The figures are generally drawn to full scale, but sometimes half-scale has been employed. Lines of projection are clearly indicated—an important factor in some of the more complicated figures. The key should prove a help to beginners, who should study well the questions and their accompanying figures.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Geology in Nubibus."—A Reply to Dr. Wallace and Mr. LaTouche.

DR. WALLACE has taught us a great deal, and among those lessons is the supreme virtue in scientific controversy of courage and candour. He must forgive me therefore for answering promptly, and I hope frankly, his last letter in NATURE. In this letter he appeals from your columns to a non-scientific

magazine in which he is writing, and where, like the sermon from the pulpit, what is said cannot be answered. This appeal is not to my taste, for I agree with the late Lord Tweeddale, that truth is never so free from difficulty as when the good grain has been thrashed out by the flails of controversy.

The position we are fighting about is too important, however, to go by default, for upon it rests a vast deal of induction in other fields besides geology.

My contention is, and I am speaking to every man of science, geologist or otherwise, that before Dr. Wallace can appeal to ice as the excavator of lake basins on level, or nearly level, plains *far* away from the slopes where glaciers grow, he must establish two postulates. (1) That ice can convey thrust for more than a very moderate distance. (2) That glaciers such as we can examine and report upon are anywhere at this moment doing the excavating work which he postulates. Without these postulates, his appeal to ice seems to me absolutely outside science altogether, and to be a mere resort to some *Deus ex machina*, such as the mediæval schoolmen based their reasoning upon.

In regard to the first postulate the experimental evidence seems to me to be conclusive, and I have quoted it in my work on the glacial nightmare. Mallet, writing on the modulus of ice, says: "A few experiments have been made which show that the height of this modulus cannot exceed a few hundred feet." "Let it be assumed, however, that it is as great as 5000 feet, or a mile. It is then obvious that a mass of ice, no matter how deep or wide, lying in a straight, smooth, frictionless valley, cannot be pushed along by any extraneous force, in the line of the valley, through a distance of more than a single mile, for at that point the ice itself must crush, and the direct force cease to be transmitted further. This, of course, is far from being the whole of the question of the transmission of force through ice, for when and wherever crushing takes place, a certain portion (though a small one) of the direct pressure is transmitted laterally by the crushed fragments, especially if mixed with water. For this to take place however, in the direction of the length of the ice-filled valley, supposes the ice must be considerably more than a mile in vertical depth." Mr. Oldham has carried the question further, and I have quoted his arguments and experiments on pages 596–597 of my book. His conclusion, after postulating a quite transcendant modulus, as tested by observation, is: "The greatest distance to which a glacier could be forced *en masse* is about five miles, so that a glacier debouching on a plain could not exert any erosive power on that plain for more than five miles from the commencement of its level course, and consequently could not scoop out a lake basin of more than that length, whatever its depth might be."

Not only does this conclusion involve the postulating of quite an impossible modulus for ice, but it also supposes that the whole thrust of the ice coming down a slope is available, which it clearly is not. A great deal of this thrust, as Mr. Irving has shown, is expended in overcoming cohesion, in causing the differential motion of a glacier, in forming crevasses which largely intercept the thrust, and in causing the well-known Bergschrund. To quote my own words, "a considerable amount of the force of the gravity contained in a glacier is used up within the glacier itself, and is not available either to give it a forward thrust along a horizontal surface, or for eroding purposes."

So far as I know, this is a perfectly candid statement of the available evidence. Regelation has nothing whatever to do with it. Directly ice crushes, the thrust is dissipated, the greater part of it passing off in the direction of least resistance. To me the case seems conclusive, but, says Dr. Wallace: "All this is beside the question from my point of view. The work of the ice on the rocks is as clear as that of palæolithic man on the flints . . . and there is clear evidence that ice *did* march a hundred miles, mostly uphill, from the head of Lake Geneva to Soleure, whatever transcendental qualities it must have possessed to do so."

This form of dogmatic argument is assuredly incomprehensible. I wonder Dr. Wallace is not afraid of the ghosts of his own recent emphatic pronouncement on the glaciation of Brazil, which he has now entirely abandoned, namely: "If the whole series of phenomena here alluded to have been produced without the aid of ice, we must lose all confidence in the method of reasoning from similar effects to similar causes which is the very foundation of modern geology."

No, true geology is not founded upon hypotheses outside the laws of nature; its secrets, when properly read, must be consistent with those laws. Nor can the geologist who hopes to see his work live, base his reasoning upon a peculiar scheme of mechanics which experiment refuses to verify.

If glaciers travelled further in former days, it was doubtless because glaciers were larger in former days, because they descended longer slopes, and had larger gathering grounds; that is to say, because the country where they grew was more elevated. All this I, of course, admit was the case. That ice could travel then any more than it can travel now over a considerable distance of level ground, or excavate hollows in its track, by virtue of the *vis a tergo* given it in its sloping cradle, is, it seems to me, a subjective dream, and not an empirical conclusion.

So much for the first postulate necessary to establish Dr. Wallace's conclusion. In regard to the second, I have little to say. Glaciers exist in many countries. In some they have retreated in historical times: in others, we can travel underneath them for some distance. I know of no case, under any conditions, where it can be shown that they have excavated rock basins, small or big. If Dr. Wallace can quote any, it would be an important addition to the case he makes. I must therefore conclude that, so far as our evidence goes, ice cannot excavate lake basins on level plains, and that it is contrary to the laws of the mechanics that it should do so.

Dr. Wallace says, "No glacialist of the extremest school would claim the rock basins of Bahia as proofs of glaciation." This is an extraordinary statement. Why, the report on these basins made by Mr. Allen, and incorporated by Hartt, was among the most powerful pieces of evidence adduced by the latter for the former glaciation of Brazil, which evidence Dr. Wallace urged upon us a short time ago was completely unanswerable. Lastly, in regard to Tasmania I do not quite follow him. He says, "No doubt the conclusions of the various writers will be fully harmonised by a more complete study of the whole subject." They are harmonised already. *They all agree* that on the plateaus and in the central district of Tasmania, where the lakes abound, there are no traces of glaciation. So far as I know, the only person who disputes it is Dr. Wallace himself, who has never been there. What needs to be harmonised is his theory with the facts as observed by all observers.

I have replied at some length to Dr. Wallace's letter, not only because I consider the issue a most critical one, but also because of the distinction of its writer, who on so many questions has taught us lasting lessons, but who on this one seems determined to set himself against the general conclusions of those geologists who have most closely and laboriously studied ice at work.

I must now turn to Mr. LaTouche, whose courteous criticism of my views appeared in a previous number of NATURE. I am not quite sure how far we differ, for he apparently repudiates the theory favoured by Ramsay and by Dr. Wallace, that the great Alpine and Scotch lakes were excavated by glaciers. He limits himself to certain rock basins in highly glaciated regions. In regard to these having been excavated by ice, Mr. LaTouche reminds me that ice is a viscous body, and moves, as Principal Forbes argued that it does, almost entirely as a viscous body. If Mr. LaTouche had favoured me by looking into my last book, he would have found a long and very laborious chapter devoted to establishing this very conclusion, but I do not see how it assists his position. A viscous body, unless the viscosity approaches that of a liquid, cannot move by mere hydrostatic pressure, since the internal friction and the resistance and mutual support of its particles prevent it. The viscosity of ice is very slight indeed, hence we cannot postulate for the nether layers of a glacier with an uneven surface the movements we should postulate in a liquid under the same conditions. With the forces known to be requisite to make it shear, it seems to me that ice cannot be supposed to move by hydrostatic pressure.

Its actual motion is due almost entirely to its layers rolling over each other as they do in pitch and other viscous bodies. Now this movement in thick ice we know is appreciable at the surface, but the same conditions of friction and of drag, already quoted, retard each successive layer as we go down, until when we reach the lowest layers the motion due to viscosity is exceedingly slight if it is even appreciable. Hence I cannot see where the mechanical agent is to come from to excavate basins, and how it is to work.

When ice is moving on a slope, and the viscous movement is helped by gravity, then no doubt the ice-foot shod with stones becomes a tolerable *eroding* agent; but I cannot under-

stand under what conditions it can become an excavating one, and how it can hollow out basins, &c.

When ice moves away from the slope which gives impetus to a glacier, the motion rapidly slackens and presently stops. The distance travelled over the level ground is a function of the weight of the glacier, of the amount of the slope, the friction of its bed, &c., *i.e.* of the elements making up the *vis a tergo*; but in the very largest glaciers, so far as observation goes, the motion rapidly ceases on level ground. This is the evidence wherever the phenomenon has been observed and reported upon.

This being so, I altogether question not only the arguments of those who champion the excavation of lake basins by ice, but also of that larger school who invoke movements of ice over level plains of many hundreds of miles in extent in order to explain the drift phenomena. They do it, so far as I know, on the ground that they cannot appeal to any other cause without doing injustice to that modern metaphysical bogey, "The Doctrine of Uniformity." My small boy might just as well, on the same principle, attribute the excavation of his porringer to the porridge in the bowl. True rock basins were no doubt very largely due to the weathering of rocks which exfoliate, and whose structure is not homogeneous. This is a very old explanation, but like many sober old inductive truths it is not so attractive nowadays as an appeal to the imagination, combined with a good, sturdy, consistent loyalty to some *à priori* postulate, which would have won the hearts of the old schoolmen. HENRY H. HOWORTH.

30 Collingham Place, Cromwell Road, November 16.

Rock Basins in the Himalayas.

THERE is one statement in the interesting communication of my colleague, Mr. T. D. LaTouche, which seems to require qualification. After a tolerably extensive experience of the Himalayas, I should be inclined to say that rock basins are of fairly frequent occurrence, of all sizes from the largest to the smallest, but they are almost without exception filled with stream deposits, and only occasionally can their formation have been due to glaciers; for they are usually found where there are no traces of glacial action to be seen, and at levels to which we have no reason to suppose that glaciers ever reached. In the hills of eastern Baluchistan, where the rainfall is much less than in the Himalayas, rock basins more or less filled by recent surface deposits are even more common, and here their origin by deformation of the surface can generally be established. The same cause probably accounts for the Himalayan rock basins, as there are abundant proofs that the elevatory movement has been far from uniform, and that the variations in its intensity have been both extensive and often extremely local. There are frequent occurrences of surface deposits which appear to have originally been formed in rock basins, but have since been cut into by the streams, owing to the corrasion of the barrier, and we may attribute the absence of lakes in the Himalayas to the rapid current and large burden carried by the streams, in consequence of which they have been able to fill up the basin, and often to corrade the barrier, as fast as it was formed.

R. D. OLDHAM.

"Composite" Dykes.

PROF. JUDD'S excellent paper in the current issue of the *Quarterly Journal of the Geological Society* (p. 536) calls to my mind some common and similar examples among the "elvans" of Cornwall (which are dykes in the ordinary acceptation of the term), and but little has been published offering some explanation of their bearing on urrounding rocks. I have observed, notably in the district of Cligga Head (nine miles N.W. of Truro), the marked difference between the structures exhibited by dykes in the parts in contact with the rock through which they intrude (in the Cligga instance Devonian slate), and their centre, amounting almost to a rock distinction.

In the appended sketches I have endeavoured to illustrate my meaning from actual instances.

Fig. 1 represents a section of an elvan or dyke outcropping slightly to the north of Cligga promontory, and from its position apparently connected with the main mass of Cligga Head granite. It bursts through the slate. The centre (*b*) of the dyke consists of a rock of homogeneous texture, quartzo-felspathic base, and some scattered porphyritic felspar crystals. The sides (*a a*) in contact with the slate (*s s*) show a rock of apparently similar base, but shot with long acicular crystals of schorl, the whole rock being of a very dark colour, due probably to the presence of wolfram.

Fig. 2 is a section of a very common form of Cornish elvan, consisting of alternate laminæ of granite (*d d*) and "schorl rock," that is, rock consisting of schorl and quartz, generally in about equal proportions (*c c*).

These bands are very common in the slates and in the granitic bosses. Further, an analysis of a typical "schorl rock" of this class showed a silica percentage of 67·6 (*vide* Judd's paper,

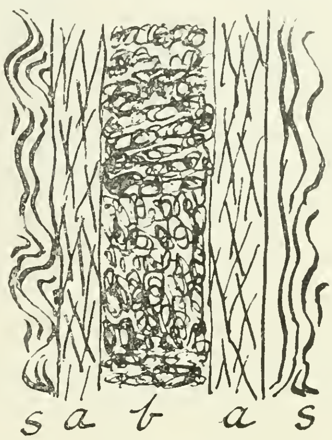

FIG. 1.

p. 545), and of a typical granitic band of 74·8 (De La Beche, "Report on Geology of Cornwall, Devon, and West Somerset," p. 189). It is very doubtful, however, if either of the above instances is a case of a dyke putting on such differences in mineralogical and chemical character in its several parts as to amount to a difference of rock species.

As De La Beche points out, the schorl rock may be simply a granite in which the felspar and mica are replaced by schorl. An instance, however, of a rock one may call "a dyke within a dyke" is the Cligga mass itself, which is nothing but a gigantic dyke. De La Beche, in his work above cited (p. 164), has figured it. The dyke is so strikingly split into layers as to

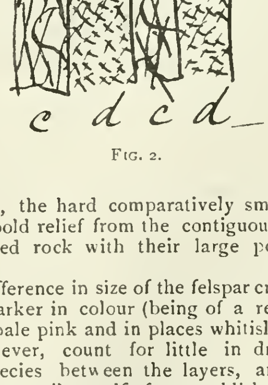

FIG. 2.

appear stratified, the hard comparatively small-grained layers standing out in bold relief from the contiguous layers of more easily decomposed rock with their large porphyritic felspar crystals.

Besides the difference in size of the felspar crystals, the harder rock is much darker in colour (being of a red hue) than the softer, which is pale pink and in places whitish. These physical differences, however, count for little in drawing a distinction of rock species between the layers, and I was unfortunately unable to avail myself of any published analyses of the different parts, but their superficial characters are so distinct as

to render the stratified appearance of the rock very marked at comparatively great distances from them.

There is in many cases a crack marking the junction of contiguous layers.

As an illustration of these "composite" dykes, I append a diagrammatic sketch representing a section of the coast about 200 or 300 yards south of the Cligga promontory, which is very difficult of approach.

A has all the appearance of a bed of sandstone, the strata curved, owing to the intrusion of the dyke *B* (granitic); *C* is an

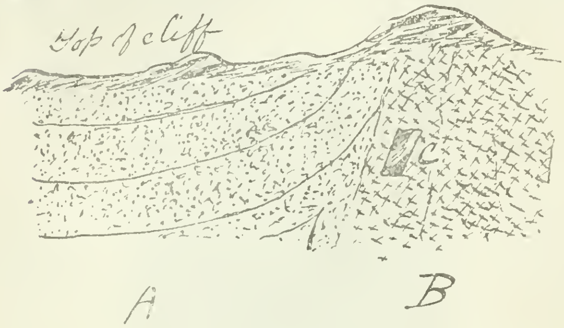

FIG. 3.

old tin burrow. As a matter of fact, each is a granitic dyke, *A* finer grained than *B*, and very like sandstone in all petrological features.

The remarkable fact is the apparent stratification of the beds *A*, which are really bands of several dykes—a continuation of those figured at p. 164 in De La Beche's book. He does not seem to have observed this instance, or at any rate does not mention it; his figure is from the cliff immediately in contact with the Cligga promontory, and north of that I have figured.

Further instances of this very interesting kind of composite dyke would help in many cases to unravel the seeming complexity of such geological features as those I have touched upon in Cornwall. HENRY E. EDE.

45 Walker Terrace, Gateshead-on-Tyne, October 4.

Weismannism.

I NEVER answer reviews, save in so far as they may be misleading on matters of fact. As this is the case with "P. C. M.'s" notice of my "Examination of Weismannism" (NATURE, November 16), I should like to say a few words touching the more important of such matters.

It seems that in seeking to do justice to all sides in the heredity question, I have been too careless in expressing my own view. At all events, any one reading the review must gather from it that I am a Lamarckian engaged in fighting the theories of Prof. Weismann. In the book, however, it is stated that I have been an adherent of the theory of Stirp ever since it was published by Mr. Galton in 1875. It is also stated that this theory is, in my opinion, identical, as regards all main principles, with that of Germ-plasm in the present phase of its numerous metamorphoses. Therefore, far from fighting the Weismannian theory of heredity, I see in all its main features, as it now stands, a "re-publication" of the one which I have held for close upon twenty years.

It is further stated that the only points of much secondary importance wherein I can perceive the two theories to differ are, (*a*), that while Galton confined himself to publishing a theory of Heredity, Weismann proceeded to rear upon this basis (*i.e.*, the hypothesis of "continuity") a further and elaborate theory of organic evolution; and, (*b*), that Weismann has not gone so far as Galton did in expressly recognising the possibility of an occasional transmission of acquired characters, in faint though presumably accumulative degrees. As regards these two points of difference, I have endeavoured to show, (*a*), that Weismann has now himself withdrawn nearly all his previous generalisations with regard to organic evolution, while largely modifying his theory of heredity; and, (*b*), that he has only to expand certain hints which he has already given—and which, if expanded, would entail much less modification of his original system than those which he has now made in other parts thereof—in order as fully to recognise as Galton did the possibly occasional transmission of acquired characters.

Hence, such opposition as I have found any reason to express with regard to Weismann's system in the latest phase of its development arises, almost exclusively, against the inordinately speculative character of his method. The history of science furnishes no approach to such a disproportion between deduction and induction.

Thus it seems to me that any writer on Weismannism who aims at impartiality must fail in his aim, if he does not give due prominence to this the most distinctive feature of Weismann's method. And, unless the reviewer is prepared to defend such a method as scientific, he has no reason to quarrel with what he calls my "hard words," since they all have reference to it, and are statements, not of opinions, but of facts.

On the other hand, I have endeavoured by "soft words" to fully recognise the great merit of Weismann's work in constituting the heredity question one of world-wide interest. And any bias that I may have with regard to this question is assuredly on the side of "continuity," although I cannot hold that the subordinate question is closed—*i.e.*, as to whether such continuity can never, under any circumstances or in any degrees, be interrupted. GEORGE J. ROMANES.

Hyères, November 20.

Correlation of Solar and Magnetic Phenomena.

MR. ELLIS, in his letter (NATURE November 9), has discussed the coincidence between Carrington's observation of a solar outburst in 1859 and the magnetic movements observed at Kew and Greenwich. He comes to the conclusion that the disturbance of the magnets corresponding to this outburst was small, and that, although many greater magnetic movements have occurred since, no corresponding manifestation has been seen, although the sun has been so closely watched.

He appears to have overlooked an observation made at Sherman, by Prof. Young, which shows a very striking *series* of coincidences, and which is described in his work, "The Sun" (p. 156), in the following words:—"On August 3, 1872, the chromosphere in the neighbourhood of a sun-spot, which was just coming into view around the edge of the sun, was greatly disturbed on several occasions during the forenoon. Jets of luminous matter of intense brilliance were projected, and the dark lines of the spectrum were reversed by hundreds for a few minutes at a time. There were three especially notable paroxysms at 8.45, 10.30, and 11.50 a.m., local time. At dinner the photographer of the party, who was making our magnetic observations, told me, before knowing anything about what I had been observing, that he had been obliged to give up work, his magnet having swung clear off the scale. Two days later the spot had come round the edge of the limb. On the morning of August 5, I began observations at 6.40, and for about an hour witnessed some of the most remarkable phenomena I have ever seen. The hydrogen lines, with many others, were brilliantly reversed in the spectrum of the nucleus, and at one point in the penumbra the C line sent out what looked like a blowpipe jet, projecting toward the upper end of the spectrum, and indicating a motion along the line of sight of about 120 miles per second. The motion would die out and be renewed again at intervals of a minute or two. . . . . The disturbance ceased before eight o'clock, and was not renewed that forenoon. On writing to England, I received from Greenwich and Stonyhurst, through the kindness of Sir G. B. Airy and Rev. S. J. Perry, copies of the photographic magnetic records for those two days. . . . . On August 3, which was a day of general magnetic disturbance, the paroxysms I noticed at Sherman were accompanied by peculiar twitches of the magnet in England. Again, August 5 was a quiet day, magnetically speaking, but just during that hour, when the sun-spot was active, the magnet shivered and trembled. So far as appears, too, the magnetic action of the sun was instantaneous. After making allowance for longitude, the magnetic disturbance in England was strictly simultaneous, so far as can be judged, with the spectroscopic disturbance seen on the Rocky Mountains."

These observations of Prof. Young's seem to invalidate Mr. Ellis's statement that "no second occurrence similar to that of 1859 has come to light," and that although there undoubtedly exists a relation between sun-spots and magnetism, "it has not yet been found possible to trace direct correspondence in details."

Cambridge, November 12. A. R. HINKS.

THE circumstances spoken of by Prof. Young, as alluded to in the accompanying letter, tell of special solar activity at the time of magnetic disturbance, observed solar paroxysms occurring apparently in correspondence with magnetic movements; but the question whether definite connection exists, is the really critical point, as in the Carrington observation of 1859. Prof. Young himself says ("The Sun," p. 159):—"*So far as appears*, the magnetic action of the sun was instantaneous. After making allowance for longitude, the magnetic disturbance in England was strictly simultaneous, *so far as can be judged*, with the spectroscopic disturbance seen on the Rocky Mountains." (The italics are mine.) Without being over-critical, it may be remarked that the terms "instantaneous" and "strictly simultaneous" are somewhat strong, in the circumstances of the case.

Feeling that too much importance had been by various writers attached to the Carrington observation, I may have been led to the expression of a too pronounced opinion thereon. Rather it might be said that direct connection is not proved. It is to be remembered that the cases of recorded occurrence together of solar and magnetic phenomena are few, whilst solar change (such as is sometimes actually observed, or as is remarked in the changed solar appearance from day to day) without magnetic action, and very frequently magnetic action without recorded solar change, both occur in greater degree than, on the supposition of direct connection between the two classes of phenomena, would be expected. Prof. Young, indeed, further says:—"No two or three coincidences such as have been adduced are sufficient to establish the doctrine of the sun's immediate magnetic action upon the earth, but they make it so far probable as to warrant a careful investigation of the matter—an investigation, however, which is not easy, since it implies a practically continuous watch of the solar surface." One main difficulty is here pointed out. Continuous magnetic registration is easily maintained, but how far the observation of solar change is adequate (in spite of the numbers of observers) for the purposes of such an inquiry is possibly somewhat doubtful. The problem of a sufficiently comprehensive and satisfactory comparison of the irregularities in solar and magnetic changes is evidently one of very considerable difficulty.

Greenwich, November 14. WILLIAM ELLIS.

Artifical Amœbæ and Protoplasm.

I REVIEWED in NATURE, No. 1251, Prof. Bütschli's recently published work "Mikroskopische Schäume und das Protoplasma." The book is distinctly polemical, and on pages 5 and 6 the author refers to his own, and his colleague Prof. Quincke's work, and states his indebtedness to the latter's investigation upon physical emulsions, but accuses him of having adopted his own view as to the structure of protoplasm, and that without acknowledgment.

"Ich habe Herrn Collegen Quincke, bevor er seine Hypothese der Plasmabewegungen veröffentlichte, mehrfach meine Ansicht ueber die wahrscheinliche Structur dieser Substanz gesprächsweise mitgetheilt und betont, dass gewisse Eigenschaften des Plasmas wohl mit dieser Bau irect zusammenhängen dürften. Quincke hat in seiner Mittheilung von 1888 das Plasma noch als einfache Flüssigkeit behandelt, von einer Schaumstructur desselben nirgends gesprochen; wenn er später (1889), nach Veröffentlichung meines ersten Berichtes (1889) die Schaumstructur betont, so kann ich darin nur den Einfluss meiner Erfahrungen erkennen, auch wenn er derselben in dieser Publication, welche über das Plasma und seine Bewegungserscheinungen handelt, nirgends gedenkt."

(*Trans.*)—In the course of conversation, and before he published his hypothesis of protoplasmic movement, I frequently mentioned my view as to the probable structure of this substance to my colleague Quincke, and I emphasised the probability of a direct relation between certain properties of the plasma and this structure. In his note of 1888 Quincke still treated the plasma as a simple fluid, and nowhere made mention of the foam-like structure. When, later on, in 1889, after the publication of my first report, he emphasises the foam structure, I cannot but recognise the influence of my own experiences, though he makes no mention of them in this publication, which treats of the plasma and of the phenomena of its movement.

In NATURE, No. 1253, a letter appeared from Prof. Quincke, stating that he "was the first to point to the foamy nature of protoplasm, which was later on further investigated by Prof. Bütschli."

Prof. Quincke is evidently annoyed that his prior claim to the discovery, if discovery it be, was not made clear by me in the review. But my duty as a reviewer was with Prof. Bütschli, whose views as to the foamy nature of protoplasm I sketched to the best of my ability, and I ventured to criticise them adversely. If Prof. Bütschli was not the first to describe the foamy nature of protoplasm, and if he was anticipated by Prof. Quincke, then it is the latter's duty, not mine, to make this clear. I could not possibly be expected to deal with such a controversy in a review, for such an extended historical inquiry as this would imply, would hardly have found acceptance.

As Prof. Bütschli distinctly states that before 1889 Prof. Quincke looked upon protoplasm as a simple fluid, the latter, in order to establish his position, has only to send definite quotations from one of his publications prior to this date, in which it is clear that the foamy nature of protoplasm was described by him.

I scarcely think that Prof. Quincke can himself have read my review, for had he done so he would hardly have accused me of slighting his well-known and valued scientific work. Prof. Quincke charges me with calling "his investigations" "toys for the physicist." I never referred to him at all in this connection, but spoke definitely of the preparations of foam as manufactured by Prof. Bütschli. I moreover would point out to Prof. Quincke that we cannot compare an "investigation" with a "toy," for one is an *action*, the other a *thing*.

I regret exceedingly that the "Q" in Prof. Quincke's name appeared as "N," and take to myself the sole responsibility. I write the capital "Q" not unlike an "N," and omitted to notice the mistake in the proofs. JOHN BERRY HAYCRAFT.

Physiological Laboratory, University College, Cardiff.

THE ROYAL SOCIETY CLUB.

THERE are not many social institutions which can point to an antiquity of a century and a half, and this is what the Royal Society Club was able to celebrate on Thursday, the 16th instant.

The club is almost, if not quite, the oldest club in existence. The Dilettanti Society, which was founded a year earlier, in 1742, is not a club, and has, from the first, imposed a fine on any of its members who should apply that designation to it.

The Royal Society Club was formally inaugurated on October 27, 1743, but its very act of inauguration recognises the existence of a still earlier body. This "Memorandum of Association" is headed as follows: "Rules and Orders to be Observed by the Thursday's Club, called the Royal Philosophers."

We hear of the Virtuoso's Club, meeting on Thursdays, among the clubs of London in 1709, and in the year 1742 the club was described by Hutton as "Dr. Halley's Club." It is possible that the inaugural meeting of October 27, 1743, may have been the reorganisation of the club after Dr. Halley's death in the previous year.

The title of "Royal Philosophers" lasted till 1786, when the dinner bills were charged to "the Royals." The full title Royal Society Club was adopted later.

The history of the club was drawn up in 1860 by Admiral W. H. Smyth, and privately printed, under the title of the "Rise and Progress of the Royal Society Club." Many interesting particulars may be gathered from this compilation.

At the very first, Fellowship of the Society was not a necessary condition of membership of the club, as it now is. Mr. Colebrooke, who was treasurer of the club in 1743, was not elected into the Royal Society till 1755.

The meetings were at first held at the Mitre Tavern in Fleet Street, for forty years from 1743. The club then moved to the "Crown and Anchor" in the Strand, where it remained until 1848, when it went to the Freemasons' Tavern. On the removal of the Society to Burlington House in 1857, the club followed it westwards to the Thatched House Tavern, and subsequently to Willis's Rooms. On the final closing of the last-named

establishment, in 1889, the club migrated to Limmer's Hotel, where it now meets.

As the club grew older, the price of its dinners grew with it, from "one shilling and sixpence, for eating," in 1743, to ten shillings in 1843, at which latter price it has remained ever since. The time of dinner has also changed first from 1 o'clock to 2, and then successively to 3, 4, 4½, 5, 5½, 6, and 6½, the time of serving now.

The bill of fare for the commemorative dinner last Thursday was copied, spelling and all, from the earliest *menu* preserved, that of March 28, 1748, and the price to the members was 1s. 6d., the same as in the earliest days of the club.

The bill of fare was as follows:—

Two dishes Fresh Salmon, Lobster Sauce.
Cod's Head.
Pidgeon Pye.
Calve's Head.
Bacon and Greens.
Fillett of Veal.
Chine of Pork.
Plumb Pudding.
Apple Custard.
Butter and Cheese.

The members are indebted to the managers of Limmer's Hotel for the readiness with which they entered into the project of reproducing a dinner on the ancient model.

As the month was November, salmon was not to be had, so that other fish was substituted. An important addition was made to the *menu*, for a haunch of venison was presented to the club by one of its members.

In early days whole bucks, haunches of venison, turtles, and barons of beef were not unfrequently presented, the donors being in each case elected honorary members for the then current session.

These contributions became rather inconvenient, and on July 29, 1779, it was "resolved that no person in future be admitted a member of this Society in consequence of any present he shall make to it."

The club consists of fifty ordinary members, and this number is increased by *ex officio* members (present or past office-bearers in the Royal Society) and by a few honorary (octogenarian) and supernumerary members, until the total in 1893 has reached sixty-one. Of these forty-four were present on the 16th, with twenty-three guests, making a total of sixty-seven.

From the earliest times each member of the club has had the privilege of bringing one guest with him, the President for the day being not limited to one. This practice of bringing guests has been generally carried out, and a study of the list of visitors given in Admiral Smyth's "History" shows that many of the leaders of European science have at various times entered their names in the club records. Berzelius, Cuvier, Gay-Lussac, Linnæus, and Volta were guests of which any club may justly be proud.

We may also fairly assert, in conclusion, that since the middle of the last century, there are but few names really prominent in British science which do not appear in the list of ordinary members of the Royal Society Club at some time of its existence.

THE DE MORGAN MEDAL.[1]

The duty has this year devolved upon the Council of making the fourth triennial award of the medal which was instituted in memory of our first President, the distinguished logician and mathematician, Augustus De Morgan. In making their award, the Council are not restricted in their choice to mathematicians of this country, or to the recognition of excellence in any particular branch of mathematical science. It will scarcely, however, be imputed to them that they have been influenced by feelings of patriotism rather than by scientific impartiality in having selected as the first three recipients of the medal, Prof. Cayley, Prof. Sylvester, and Lord Rayleigh. The position of those eminent mathematicians suffers no depreciation, if our survey is extended beyond the borders of our own country. On the other hand we shall, I think, be equally exempt from adverse criticism in the choice we have this year made of Felix Klein, Professor of Mathematics in the University of Göttingen, as the next recipient of the honour which we are privileged to confer.

Prof. Klein, who has for many years been enrolled in our books as an honorary member of our Society, has attained the highest distinction as a mathematician. In estimating the value of his work, a mere consideration of the advance due to him in our knowledge of the details of special subjects would be sufficient to place him in the first rank; the wide influence of his work must be apparent to anyone who studies the memoirs of writers, of whatever country, on those subjects to which he has set his hand. Let me in particular refer to his contributions to the geometry of complexes, and to non-Euclidean geometry, to his memoirs on the theory of equations, on the transformation of elliptic functions, on the general theory of functions, especially in exposition and development of Riemann's theory, to his discussion of Riemann's surfaces, and, in more recent times, his researches on Abelian and Hyperelliptic functions, to his treatment of the polyhedral functions, automorphic functions, and of the elliptic Modular functions, the last of which is expounded in the treatise by Fricke on the subject. One must not forget to record the fact that his important memoir on the transformation of elliptic functions in the *Mathematische Annalen*, vol. xiv., was preceded by a communication made to our Society in 1878; Prof. Klein thus doing us the honour of indicating in advance the principal results he had obtained (*Proceedings*, vol ix. p. 23).

But, in the necessarily brief remarks to which I must limit myself this evening, to indicate Prof Klein's claims to distinction by dwelling upon individual subjects which he has treated, would, I think, be wanting in perspective and proportion. Great as is the reputation which he has acquired in connection with particular branches of mathematical research, that which would seem to be his especial merit is the comprehensiveness of his view, and the uniformity of his treatment. For him the study of one of his special subjects is the study of all; the binding influence b ing the theory of discrete groups, a theory he has made his own. With this unity of conception he combines a great power of simple, elegant, and interesting expression. The expositions of his method contained in his early "Comparative Review of Recent Researches in Geometry," and his more recent "Lectures on the Icosahedron," in which the formal identity of investigations apparently the most diverse is made apparent, belong to the romance of mathematics. The important influence which his mode of investigation has had and is destined to have on the progress of the higher mathematics, the encouragement of largeness of view, rather than the elaboration of minutiæ, and the stimulating influence he exercises upon pupils who now hold positions of eminence in Germany, must take a foremost place among the grounds upon which we honour Prof. Felix Klein to-day by the award to him of the De Morgan Medal.

[1] Address to the London Mathematical Society, on the occasion of the presentation of the De Morgan Medal, November 10, 1893, by the President, A. B. Kempe, F.R.S.

NOTES.

The agricultural exhibit of Sir John Lawes and Sir Henry Gilbert at Chicago appears to have been much appreciated by our American cousins. The Association of American Agri-

cultural Colleges and Experiment Stations have passed a special resolution expressing the value they attach to the exhibit, and the Director-General of the Exposition has forwarded the same to England, with the added thanks of the Exposition, for "the great benefit done to American agriculture by this excellent and instructive exhibit."

A PASTEUR Institute has been opened in New York, with Dr. Paul Gibier as its director.

M. O. CALLANDREAU, of the Paris Observatory, has been appointed Professor of Astronomy at the École Polytechnique.

DR. TREADWELL has been appointed Professor of Analytical Chemistry in the University of Zurich.

DR. A. K. E. BALDAMUS, known for his work in connection with ornithology, died on October 30, at the age of eighty-two.

MR. J. BAILEY DENTON, whose name has long been known to agriculturists and civil engineers, died on November 19, at Stevenage, Herts, in his seventy-ninth year.

WE regret to announce the death, at the age of eighty-one, of M. Chambrelent, a member of the Rural Economy Section of the Paris Academy of Sciences.

MR. WILLIAM DINNING, of Newcastle, a lover of natural science and a promoter of its interests, died on November 13. Shortly before his death, he offered his collection of fossils from the coal measures to the Newcastle Natural History Society, on the condition that the society would provide cases to properly exhibit it and the collection already existing in the local museum. The society was without the necessary means, but Lord Armstrong has promised to contribute a sum of £1500 for this purpose. Mr. Dinning was an engineer by profession, but all his leisure was devoted to scientific pursuits. His death will be greatly felt in local circles.

IT is reported that a severe shock of earthquake was experienced on November 17 in Kashan, Western Asia, a large part of the town being destroyed. Great damage was also done at Samarcand.

MR. LLOYD BOZWARD, Worcester, informs us that on November 17 a fine shower of Leonid meteors was seen throughout the night. The meteors are said to have been so numerous that several persons unacquainted with their nature mistook the display for an exhibition of fireworks.

THE Swiney prize of a cup, value £100, and money to the same amount, to the author of the best published work on jurisprudence, will be awarded by the Society of Arts and the College of Physicians in January next. The prize is awarded every fifth year, the recipient in 1889 being Dr. C. Meymott Tidy, for his work entitled "Legal Medicine."

AT the beginning of next year the first number of an "Index der gesamten chemischen Litteratur" will be published by H. Bechhold, Frankfort. The index will appear monthly, and after the end of each year an index comprising all the papers published during the year in pure and applied chemistry will be issued. The editor of the forthcoming publication is Dr. Julius Ephraim.

MESSRS. W. H. ALLEN AND CO. have in preparation a series of volumes founded upon Jardine's Naturalist's Library. The editor of the series, Dr. Bowdler Sharpe, will undertake several of the ornithological volumes. The authors of other sections are Mr. R. Lydekker (Mammalia), Mr. H. O. Forbes (Mammalia and Birds), Mr. W. R. Ogilvie Grant (Birds), Mr. W. F. Kirby (Insects), Prof. R. H. Traquair, F.R.S. (Fishes). The first volumes will be issued early in 1894, and will consist of British Birds, vol. i., by Dr. R. Bowdler Sharpe; Monkeys, by H. O. Forbes; and Butterflies (with special reference to British species), by W. F. Kirby.

WE have previously referred to the fact that on the first of this month Italy adopted the time of Central Europe. All the Italian time-tables have, by order of the Minister of Public Works, been printed with the hours marked up to twenty-four from midnight to midnight. The railway clocks have also been modified, and the hours from 13 to 24 printed in red Arabic characters in a circle interior to the old one. It may be well to remember that at the Paris Exhibition in 1867, Sig. G. Jervis, the Keeper of the Royal Industrial Museum of Turin, exhibited a clock face having a double series of hours, the higher numbers being placed on the exterior circle on account of the greater space there available. He also exhibited a time-table drawn up on the 24-hour plan, and possessing many advantages over those in use even at the present time. Mr. Jervis has thus had the satisfaction of seeing the adoption of the improved clock-dial and the 24-hour time-table, proposed by him nearly a third of a century ago.

DURING the past week this country has experienced some of the most destructive, if not the most violent storms that have occurred for some years. The reports received by the Meteorological Office on Thursday morning, the 16th instant, showed that a deep disturbance was approaching our shores, and storm signals were hoisted on our coasts. On the afternoon of that day the storm broke with great violence over the west of Ireland, the direction of the wind being south-easterly with a moderately high temperature, while the barometer was below 29·5 inches. The centre of the storm passed across England and Scotland, taking the ordinary north-easterly course, and by 6 p.m. on Friday it lay off the extreme north-east coast of Scotland, and the barometer had fallen to 28·5 inches; the wind, as usual in the rear of storms, shifted to the north-westward, causing a sudden fall of temperature with heavy snow and hail in many places. At this point the track of the disturbance took a very unusual direction, and during Friday night the centre moved quickly to the south-eastward down the North Sea, and at 8 a.m. on Saturday, the 18th instant, the centre lay off the north-east coast of England, while the pressure rose rapidly over the western portion of the kingdom, causing steeper gradients and bitter northerly and north-easterly winds. The storm first broke over London and the southern parts of the country on Saturday afternoon, and blew in terrific squalls during the whole of Saturday night, the centre again resuming an easterly course across the North Sea to the Dutch and North German coasts. The greatest strength of the wind appears to have been experienced near Holyhead, where the force on Saturday morning was reported as 12 of the Beaufort scale, while force 11 was reported from Wick and Scilly. In the neighbourhood of London the heaviest gusts were experienced in the early part of Saturday evening; the anemometer at Greenwich recorded a pressure of 17 pounds on the square foot at about 6 p.m. On Sunday and Monday the wind force was still high in the south-east of England, as well as in the English Channel, and a very high sea was running on our coasts. The storms were also very violent on the other side of the Channel, and were accompanied by heavy falls of snow in many parts of the Continent.

THE Pilot Chart of the North Atlantic Ocean shows that the first half of October was marked by much bad weather north of latitude 45° between Newfoundland and the British Isles. One of the storms caused immense loss of life and property in Louisiana, owing to a tidal wave encroaching over the low-lying lands. A supplement issued with the chart shows clearly the actual weather conditions between the 23rd and 28th of

August last, west of longitude 50° W. During this period two severe storms occurred; the first struck the coast in the vicinity of New York, where much damage was done to shipping, the second struck the coast near Savannah, and occasioned frightful loss of life along the coasts of South Carolina and Georgia, the barometer falling to 28·29 inches at 6 a.m. on August 28. This was the storm referred to in our issues of 31st August and 7th September.

The annual meeting of the Royal Geological Society of Cornwall was held at Penzance on November 10, when the president, Mr. Howard Fox, delivered an address, in which he reviewed the past history of the society. In the course of his remarks, he said that the rocks of West Cornwall had been subjected to precisely the same conditions as those of Moffat and Girvan, in South Scotland, described by Prof. Lapworth. They show, in fact, a repetition of the same phenomena, except that as yet no band of fossiliferous rock characteristic of a special geological zone has been discovered as a horizon of reference. It is, therefore, worth consideration whether the radiolarian cherts of Mullion Island, described in the *Quarterly Journal of the Geological Society* for this year, will not answer the same purpose. The Mullion Island cherts consist of easily-recognised bands of mostly black flint-like rock, generally reticulated with thin but conspicuous white quartz veins. They are extremely hard and resistant of both atmospheric and subterranean agents of destruction. They are of sufficient thickness to form a distinctly marked feature in the ascending sequence, and having been originally deposited on the floor of a deep ocean as radiolarian ooze, they necessarily occupy a wide horizontal extent of country. They occur in distinct bands, mostly in shales or crushed dark slates; they break with a conchoidal fracture, and when sheared or impure the microscope can generally determine their nature. The fossils are radiolarian deep-sea forms like those of the present day. Messrs. Teall and Lapworth have traced these cherts with Mr. Fox for 800 yards in the cliffs and on the foreshore north of Porthallow in-Meneage, and during the past summer they have been traced at intervals through the parishes of Veryan, Gorran, and Caerhayes. Pebbles have been found on the north coast, which under the microscope show radiolaria with their structure still visible, but the parent rock has not yet been found *in situ*. It will therefore be agreed that these cherts most certainly should be traced wherever they appear in Cornwall. Their age is undoubtedly Ordovician, yet the precise zone to which they belong can only be determined by discovering some typical fossils in the shales and slates associated with them. In South Scotland officers of the geological survey have recently traced such cherts with radiolaria from sea to sea just beneath the Llandeilo rocks, fixing horizons exactly. The cherts in Cornwall, possibly of the same age, and certainly of the same character, are equally promising in the midst of the entangled rocks around, to form the datum line, or clue to the succession.

A collection of land and marine shells of the Galapago Islands was made during the voyage of the U.S. Fish Commission steamer *Albatross* in 1887–88. A report on this mollusc fauna, prepared by Dr. R. E. C. Stearns, has recently been issued from the U.S. National Museum. It is not an exhaustive review of the collection, but includes the principal collections previously made, and also a few notes of interest. The extreme tenacity of life of land snails in every stage of growth is well known. Dr. Stearns gives the following instances that came under his own observation:—"In December, 1865, the Stearns collection, now in the National Museum, was enriched by the acquisition of several examples of *Helix Veatchii*, Newcomb, now regarded as a variety of *H. areolata*, that were collected by Dr. Veatch on Cerros or Cedros Island off the coast of Lower California in 1859. The specimens were given by Dr. Veatch to Thomas Bridges, and upon the death of the latter came into my possession with the remainder of the Bridges shells. One day, upon a careful examination, I discovered that one of the specimens was apparently still alive, and placed it in a box of moist earth; after a while it protruded its body from the shell and commenced moving about, and seemed to be no worse for its long fast of at least *six years*. *H. Veatchii*, it will be observed, beat the time of the famous British Museum example of *H. desertorum*, which lived without food within a few days of *four years*. In March, 1873, Prof. George Davidson, of the United States Coast Survey, while at San José del Cabo, Lower California, collected a number of specimens of *Bulimus pallidior*, and subsequently gave me a part of them, which I put in a box, where they remained undisturbed until June 23, 1875, when they were placed in a glass jar with some chick-weed and a small quantity of tepid water. They soon woke up and began to move about apparently as vigorous as ever after their long nap of *two years, two months, and sixteen days.*"

The delicacy of the sense of taste among Indians has been tested by Mr. E. H. S. Bailey, and the results compared with those obtained from whites (*Kansas University Quarterly*). The method of testing was by solutions of different strengths, the substances quinine sulphate (bitter), sulphuric acid (sour), bicarbonate of soda (alkaline), cane sugar (sweet), and common salt (salt) being selected as representing classes of the common familiar substances most likely to be recognised. The only one of these that experience has shown is not familiar is the alkaline taste. From an examination of the results it appears that the order of delicacy is about the same for the two races. By this it is meant that the smallest proportion of quinine was detected; acid solutions come next in the order of action upon the organ of taste, and then salt. In the case of whites, sweet solutions were more detectable than alkaline ones, but the reverse was the case with the Indians. This does not count for much, however, as the Indians had great difficulty in distinguishing between the alkaline and salt solutions. As might have been expected, the ability to detect the different substances when they are in very dilute solution is less in the Indians than in the whites. The males of both races are able to detect a smaller quantity of salt than the females, but in all other cases the females appear to have the more delicate organ of taste.

The question as to whether gases are capable of emitting heat has been investigated by many physicists, most of whom have come to the conclusion that the characteristic spectra of glowing gases are chiefly, if not solely, due to some chemical action going on within the gas. Hittorf heated air in platinum tubes a few centimetres long over a Bunsen, and Siemens treated air, carbonic acid, and steam in a similar manner, using longer tubes and higher temperatures. Both were unable to discover any radiation by the gases when thus simply heated, and Pringsheim, after more recent work, came to the conclusion that emission spectra cannot be obtained by simple heating. Mr. F. Paschen has, however, quiet recently (*Wied. Ann.* No. 11) succeeded in discovering and mapping such spectra by a modification of Tyndall's experiment with gases rising from an incandescent body, substituting the bolometer for Tyndall's thermopile. The hot body employed was a spiral band of platinum forming a narrow tube, which was heated by passing an electric current through the platinum. The gases were sent through this spiral, and thus acquired a temperature of about 1000° C. The temperature was measured by means of a platinum : platinum-rhodium thermocouple with an excessively small junction. The spectrum was formed by a fluorspar prism

and two concave mirrors, adjustable automatically to minimum deviation for any wave-length. The gases examined were air, oxygen, carbon dioxide, and steam. Only the last two gave positive results, some small deflection in the first two being due to slight traces of moisture. Carbonic acid showed a very sharp maximum far in the infra-red. The bolometer strip was too broad to determine whether it was a line or a band, but it is most probably a somewhat ill-defined line. Steam showed about eight maxima, which must be described as bands. A comparison of the spectrum of the Bunsen flame with that of the hot products of combustion arising from it showed that the spectra obtained are similar and of almost equal intensity; so that it is very probable that the spectra of hot gases are chiefly due to temperature, and not to chemical action. A curious and hitherto unexplained observation is that of a slight shifting of the maxima towards the more refrangible end of the spectrum when the temperature is lowered.

To determine correctly the values of the critical constants of a substance is a matter of considerable difficulty: the estimation of the critical temperature, however, is generally believed to be both expeditious and accurate. The usual method of taking an observation of the critical temperature consists in heating the liquid in contact with its saturated vapour in a closed space to a temperature above the critical temperature, allowing the substance to cool, and noting the temperature t_c at which the meniscus of the liquid just appears in the misty contents of the closed space. In the current number of *Wiedemann's Annalen*, Herr Galitzini gives evidence to show that t_c thus determined, although it is independent of the amount of substance contained in the closed space, is lower (it may be considerably lower) than the true critical temperature, or the temperature at which liquid and saturated vapour have the same density. By very slow and regular cooling he also finds that the peculiar misty appearances which are usually held to be invariably associated with the critical state are not observed. Amongst other conclusions, his experiments, which it is to be noted were made on ether, lead him to believe that at temperatures even considerably higher than the critical temperature a substance at constant pressure may have different densities, different in some cases to the extent of 25 per cent. This last result the author attributes to the presence of molecular complexes in the substance: if its validity is established, it will of course overthrow the generally accepted idea that at any temperature above the critical temperature for a given value of the pressure there is only one value of the volume.

An interesting paper on the various electric wave systems obtained by Lecher's method has been communicated to the R. Accademia della Scienza di Torino by Signor Mazotto. The effect of varying the lengths of the primary and secondary wires, and the distance apart of the plates of the condensers, has been studied. As an indicator of the points of maximum difference of potential along the wires, the author uses two short wires partly coiled round india-rubber tubes, which slide along the secondary wires, the ends of the wires being brought to within about 2 cm. of each other. If, when the apparatus is working in the dark, the fingers are brought near the platinum tips of these wires, two small luminous stars appear at these tips when the bridge over the secondary is in the vicinity of a node. When at a node these sparks become very conspicuous, even without the presence of the fingers. This indicator is said to have the advantage over the Geissler tube used by Lecher, that it shows more distinctly the maxima and minima, is less fatiguing to the eyes, and less capricious in its action. The number of nodal systems formed when, the primary system being kept constant, the bridge on the secondary wires is moved to different parts, were found to be more numerous than Lecher's observations would seem to indicate. The "harmonics" of the fundamental system were not the only higher systems that were produced, it being found possible, by altering the position of the bridges to produce any system intermediate between two harmonics It was also found, when the second bridge was placed at a fixed point, that the nodal systems obtained by moving the first bridge were independent, in position and intensity, of the state of the system beyond the second bridge. The wave-lengths obtained experimentally were compared with those given by the formula of Salvioni, and found to agree fairly well. The curves obtained by the author, and a full account of his method, has been published in the *Electrician*, vol. xxxii. p. 60.

The following translation of a reply given by Prof. Galileo Ferraris to a young lady who asked what electricity was, is given by the *Electrician*. Prof. Ferraris has conferred a great benefit on all those who are supposed to have any knowledge of that magic science electricity, and are therefore continually being asked this question, though whether the reply satisfied the questioner is rather doubtful. His reply was:—"Maxwell has demonstrated that luminous vibrations can be nothing else than periodic variations of electro-magnetic forces; Hertz, in proving by experiments that electro-magnetic oscillations are propagated like light, has given an experimental basis to the theory of Maxwell. This gave birth to the idea that the luminiferous ether and the seat of electric and magnetic forces are one and the same thing. This being established, I can now, my dear young lady, reply to the question that you put to me: What is electricity? It is not only the formidable agent which now and then shatters and tears the atmosphere, terrifying you with the crash of its thunder, but it is also the life-giving agent which sends from heaven to earth, with light and heat, the magic of colours and the breath of life. It is that which makes your heart beat to the palpitations of the outside world, it is that which has the power to transmit to your soul the enchantment of a look and the grace of a smile."

The current *Comptes Rendus* contains an important correction to the numbers given by M. Blondlot for the velocity of an electric disturbance in high conductivity copper (*Comptes Rendus*, October 23). The values were expressed in kilometres per second instead of thousands of kilometres per second, so each of the velocities given in our issue of November 9 (p. 37) must be increased by one thousand, in order to be correct.

A very important paper, by Dr. Uschinsky, on the cultivation of pathogenic bacteria in media, devoid of all albuminoids, appears in the *Archives de médecine expérimentale*, No. 3, 1893. Pathogenic organisms thus grown do not lose their virulent properties and, moreover, elaborate toxic substances, for on passing the media in which they have been cultivated through a Chamberland filter, the filtrate was found to be toxic. In a more recent paper, published in the *Centralblatt für Bakteriologie*, vol. xiv. No. 10, 1893, Dr. Uschinsky states that in order to obtain more satisfactory growths of the bacteria in question, he has introduced some modifications into the composition of the culture medium, which now affords as suitable a pabulum for their cultivation as ordinary bouillon. The following is the composition of this non-albuminous medium:—Water, 1000; glycerine, 30–40; sodium chloride, 5–7; calcium chloride, 0·1; magnesium sulphate, 0·2–0·4; dipotassium phosphate, 2–2·5; ammonium lactate, 6–7; sodium aspartate, 3·4. The organisms of cholera, diphtheria, tetanus, typhoid and others have all been grown successfully in the above. The poisonous substances elaborated by bacteria are, therefore, not necessarily due to their decomposition of the albumen contained in the ordinary culture media employed, but must rather be regarded as the result of synthesis; the materials produced, says Dr.

Uschinsky, belonging in all probability to the proteid bodies, and bearing much resemblance to ferments.

Dr. Uschinsky has made a special study of the tetanus bacillus when grown in this medium, and has examined in some detail the nature of the toxic products thus elaborated. A more satisfactory growth of this organism was procured by adding from one to two per cent. of grape-sugar to the solution, and the anaërobic conditions necessary for its cultivation were obtained by pouring liquid paraffin on the surface. The filtrate of such tetanus cultures was about equal in virulence to that derived from ordinary broth-cultivations of the bacillus. On the other hand, the poisonous properties of the former were far more easily removed than was the case with the broth-cultures, being destroyed by precipitation with alcohol, and also frequently by evaporation *in vacuo* at 33-36° C., this being especially the case when the latter was carried out in the presence of light. By addition of strong alcohol a precipitate was obtained, in which, besides salt, small quantities of albuminous bodies were present, as indicated by Millon's reagent and the xanthoproteic reaction. This precipitate was, however, without any toxic properties.

The second edition has been issued of a general guide to the Manchester Museum, by Mr. W. G. Hoyle, Keeper of the Museum. The book should be useful in directing attention to the most important specimens, and explaining their character. Its value would be greatly increased, however, by the addition of an index.

"A Bibliography of Vertebrate Embryology," by Mr. C. S. Minot, has been published by the Boston Society of Natural History. The titles are grouped into subjects, and the subjects are alphabetically arranged, so there is no difficulty in finding the original source of any paper, the title of which is known. An index of authors is also given to facilitate reference. Biological investigators will find the bibliography of great assistance.

The volume of selections from the philosophical and poetical works of Miss Constance C. W. Naden, compiled by the Misses E. and E. Hughes, and published by Messrs. Bickers and Son, is one of the daintiest that we have seen for some time. The selections from her essay on induction and deduction contain some remarkably fine expressions, and many other parts of the book are of great interest.

Mr. P. Anderson Graham's "All the Year with Nature" (Smith, Elder, and Co.) contains a number of reprints of articles originally contributed to various magazines. The author has a chatty style, and his heterogeneous collection will serve to while away an hour or two. The connection of many of the articles with the seasons is not very apparent, and some of the statements are not scientifically accurate, but, taken as a whole, the book is well worth reading.

Part I. of the sixth edition of Prof. Michael Foster's well-known "Text-Book of Physiology" has been published by Messrs. Macmillan and Co. It comprises the first book of the original volume, and deals with the blood, the tissues of movement, and the vascular mechanism. A number of important modifications have been made in the section devoted to the phenomena and mechanism of the heart-beat, but with this exception few changes have been introduced. Since the publication of the first edition, seventeen years ago, Prof. Foster's work has been recognised to be the best of its kind, and the issue of a new edition shows that it retains its position as a physiological "classic."

The fourth volume of Alembic Club Reprints, published by Mr. W. F. Clay, Edinburgh, is before us. It deals with the foundations of the molecular theory of gases, and comprises papers and extracts of papers by Dalton, Gay-Lussac, and Avogadro. There is no better way of studying the development of an idea than by reading such reprints as those issued under the auspices of the Alembic Club, for they enable the student to see the many difficulties that have to be overcome before a theory crystallises into shape. We therefore welcome this last addition to an excellent series of books.

The Cambridge University Press has published the first volume of the series of manuals of biological science edited by Mr. Arthur E. Shipley. The book to which we refer is "Elementary Palæontology," by Mr. Henry Woods. In it the author gives a concise account of invertebrate palæontology, chiefly considered from a stratigraphical point of view. The plan of the book is excellent, the zoological features of each group being first described, then the genera of importance geologically are classified, and with this knowledge the student is able to understand the following section dealing with the distribution of the group. Instead of giving archaic illustrations of genera, Mr. Woods includes figures required to explain structure and terminology. The student will benefit by this change. Remarkable pictures of perfectly preserved fossils may suit the popular mind, but the student must study fossils in collections, and he needs more detailed instruction concerning their characteristics. As an introduction to the study of palæontology, Mr. Woods' book is worthy of high praise.

Notes from the Marine Biological Station, Plymouth.—The past week has been one of the stormiest of the year. Work outside the Sound was quite impossible in our small boats, and even within the harbour was attended with difficulties. The captures included specimens of the Actinian *Cylista viduata*, and of the Dorididæ *Platydoris planata*, *Ægirus punctilucens* and the scarlet *Rostanga coccinea* upon the red incrusting sponge on which it feeds. From several hauls of *Antedon rosacea* a small number of the Polychæte commensal *Myzostomum* were obtained. The dogfish in the aquarium (*Scyllium catulus* and *canicula*) have begun to breed.

The additions to the Zoological Society's Gardens during the past week include a Mozambique Monkey (*Cercopithecus pygerythrus*, ♂) from East Africa, presented by Mr. Bayes; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. C. E. Morres; two —— Jerboas (*Alectaga jaculus*) from Persia, presented by Capt. R. A. Ogilby, F.Z.S.; a Tuatera Lizard (*Sphenodon punctatus*) from New Zealand, presented by Mr. Chas. Smith; a Lion (*Felis leo*, ♀) from West Africa, an American Bison (*Bison americanus*, ♀) from North America, deposited; a Cunning Bassaris (*Bassaris astuta*) from Mexico, purchased.

OUR ASTRONOMICAL COLUMN.

Mechanical Theory of Comets. — Prof. J. M. Schaeberle, in the *Astronomical Journal*, No. 306, communicates a "preliminary note on a mechanical theory of comets," this being "a strictly logical consequence of the mechanical theory of the corona." The principles which serve as a basis may be said very briefly to be the following. Any given solar eruption gives rise to both prominences and streams. The ejective force being the same, the mass of a given volume of coronal stream is less than that of a prominence. Assuming mean density of coronal stream to be one-seventh of that of accompanying prominence, the same explosive force which during the last eclipse sent prominences to a height of 80,000 miles, will send coronal matter forming the streams to an infinite distance. Coronal streams extend far, then, into space. The densest portion of the stream is located at the point of minimum velocity, and the coronal streams visible in the last total eclipse were, Prof. Schaeberle says, according to his photographs, apparently most dense in the higher regions,

proving that the matter was in rapid movement. The mechanical theory of comets supposes coronal streams to issue from the sun at all angles. These streams will penetrate far into space (some crossing one another). The atmosphere of a comet on striking these streams will in projection be in the form of luminous, nearly concentric, arcs, the greatest brilliancy being near the most advanced part of each stratum. More than one coronal stream will produce in the comet multiple tails, the angles between the tails being a function of the velocities of motion, and the inclinations of the streams. An examination of the cases where a tail is turned towards the sun is explained by a coronal stream, having a less velocity than that of the receding comet, thus producing such a phenomenon the moment the stream is entered. Prof. Schaeberle, at the conclusion of the papers, refers to a satisfactory explanation of the "Gegenschein," and also to a plausible explanation of the Aurora, both based on the coronal streams.

THE NEW STAR IN NORMA.—When the announcement of the discovery of this star by Mrs. Fleming reached Prof. F. C. Kapteyn, a search was made by him through his manuscript of his photographic Durchmusterung for this region, with the result (*Astronomische Nachrichten*, No. 3196) that he found the following star, which is "wohl fast ohne Zweifel" identical with Mrs. Fleming's. Its position is

Phot. Mag.	R.A. 1875·0	Decln. 1875·0.
9·2	15h. 21m. 0.5s.	−50° 9′·7

The plates which he had that contained this part of the heavens were taken in 1887, on June 25, July 25, and August 2; and in 1890, on April 29 and May 2. An examination of these showed that on the first three dates the star was not visible, but the last two distinctly indicate it as a star a whole magnitude brighter than the faintest star on the plate. A comparison of its brightness with the following three stars in its neighbourhood was made.

	Mag. in Phot. Diam.	R.A. 1875·0. h. m. s.	Decln. 1875·0. ° ′
(a)	9·2	15 20 51·0	−50 21·4
(b)	9·1	20 59·0	21·5
(c)	9·1	21 35·0	9·4

The results show that Mrs. Fleming's star is brighter than (a), scarcely dimmer than (b), and a little dimmer than (c). Its magnitude then in July and August, 1887, could not have been more than 9·2.

THE NATAL OBSERVATORY.—Mr. Nevill, the Government Astronomer for Natal, has to work under great difficulties. The grant of £800 per annum, made by the Natal Government to the Observatory, is certainly not enough to keep the establishment efficient. When the Observatory was first erected it was a substantially built, rectangular red brick edifice, carrying a light wooden upper structure, which formed equatorial and transit rooms, but there was only one room below, and this had to serve the double purpose of a computing room by day and sleeping room by night. Mr. Nevill has asked the Government to give him more accommodation, but his application has not been granted, the plea being shortness of funds; so he has had extra rooms built entirely at his own expense, and even now the four assistants of the Observatory work in a room which is nothing more than an enclosed verandah. The principal points under investigation at the Observatory are: the parallactic inequality in the motion of the moon, the lunar diameter, the effects of irradiation and its variations upon the moon's apparent semidiameter, and lunar libration.

MAGNITUDE AND POSITION OF T AURIGÆ.—The current *Comptes Rendus* (November 13) contains a number of observations of Nova Aurigæ, made by M. Bigourdan, at the Paris Observatory. The star's magnitude was compared with that of neighbouring stars on October 10 and 12, and on November 8, 11, and 12. The observations show that from the middle of October to the 8th inst. the light diminished very definitely, and afterwards increased, but on the date of the last observation it had not attained the magnitude observed on October 10. In 1892 M. Bigourdan micrometrically measured the position of the Nova with respect to a neighbouring star, and a repetition of his measurements, after an interval of eighteen months, shows that no change of position has taken place.

PERIOD OF JUPITER'S FIFTH SATELLITE.—Prof. E. E. Barnard's new measures (*Astronomy and Astro-Physics* for November) for the times of elongation of the fifth satellite give a period

P = 11h. 57m. 22·56s.

The value obtained from his last year's value was

P = 11h. 57m. 23·06s.

While Mr. A. Marth, from the same observations, derived a period of

P = 11h. 57m. 21·88s.

The new determination falls, as will be noticed, nearly midway between the two values quoted, and covers a period of 743 revolutions of the satellite.

GEOGRAPHICAL NOTES.

THE fate of the Bjorling exploring expedition, concerning the safety of which much anxiety has been felt in Sweden, has now been ascertained. Messrs. Bjorling and Kalstennius, two young Swedish naturalists, hired a small schooner, the *Ripple*, at St. John's, in June, 1892, and set out for a collecting trip along the west Greenland coast, accompanied by a crew of three men. After leaving the Danish settlements on the west coast last summer, no further news was received from the expedition, and the captains of the whaling vessels at work in Davis Strait this summer were specially requested to look for traces of the *Ripple* and her party. Captain McKay, of the Dundee whaler *Aurora*, who returned last week, reports that he visited the Carey Islands at the entrance to Smith's Sound on June 17 this year, and found there the wreck of the *Ripple*, a number of documents, and the body of one of the ill-fated crew. One of the papers written by Bjorling on August 17, 1892, on which day he had visited the Carey Islands to get provisions from the cache left by Sir George Nares, stated that on leaving the schooner ran aground, and the party had to land. A later note, dated October 12, shows that they attempted to reach Foulke's fjord to winter there, but after reaching Northumberland Island circumstances compelled their return. At the date of writing Bjorling intended to start immediately to endeavour to reach the Eskimo settlements at Cape Faraday or Clarence Head in Ellesmere Land, with the hope of returning to Carey Islands by July 1, 1893, to meet any whaler. In case of not finding a vessel he intended to push on to the Danish settlement. On receiving this news Captain McKay at once headed for Ellesmere Land, but the ice closed in, and he had to turn back. As the provisions would only last until January 1, it is to be feared that the whole party has perished, unless they were successful in reaching the Eskimo. If they did so, and were subsequently able to make their way to the Danish settlements, there may still be hope, but no news can be received until next summer.

THE *Times* announces that the Peruvian Government has awarded a gold medal to Mr. Clements R. Markham, F.R.S., President of the Royal Geographical Society, for the great services he has rendered to Peru in elucidating its geography, and in giving expression "with upright impartiality" to the facts of its history.

MR. W. H. COZENS-HARDY, who has just returned from a summer spent in exploration on the borders of Montenegro and Albania, has succeeded in making a number of observations of high geographical value. He has been able to lay down on a map for the first time the present frontiers of the principality, and from his knowledge of Slavonic languages and the free access accorded to him to the Montenegrin archives, he can also give a most interesting account of the past changes in the boundaries, furnishing, in fact, a chapter in the historical geography of the Balkan peninsula.

THE Arctic skipper Hans Johannensen, of Hammerfest, Norway, has heard from old Yakutsks that from the highest points of the northern shores of the New Siberian Islands a lofty land has been discerned to the north-west, at a distance of about fifteen nautical miles. He thinks, therefore, that should Nansen not steer too close to the coast, this new land might be seen from the masthead. And should the state of the ice be at all favourable, Nansen will, in all probability, attempt to take up his winter quarters there instead of the New Siberian Islands.

FROM a recent number of the *Kölnische Zeitung* we learn the somewhat remarkable fact that Cologne is the largest city in Germany, taking account of the area it covers, Berlin coming only fourth in order. In Cologne, however, only eight per cent.

of the area is built upon, the remainder being streets and open spaces.

The Paris Geographical Society has awarded the grand prize for geographical research to M. Maistre, for his great journey from the Congo to the Shari.

FLAME.[1]

THE subject on which I have the honour to address you this evening is, I am aware, one of the most hackneyed among the topics that have served for popular scientific lectures. I can only hope that it has not quite lost its charm. The chemist is often twitted with having to deal with mere dead soulless things, which at the best only set themselves into angular and unpalpitating crystals. There may be a certain amount of truth in this, but in flames we surely have phenomena of some liveliness. Our flame must be fed; it has its anatomy and varied symmetry; it is vigorous, mobile, and fleeting. I do not wish to make extravagant claims, but I do think that one may be excused for feeling almost as much interest in the study of flame as, for example, in the contemplation of the somewhat torpid evolutions of an amœba or the circulation of water in a sponge. To our guileless ancestors, at any rate, flame was a phenomenon of the rarest mystery; unable as they were to discriminate between the material and the immaterial, unable to track the solid or liquid fuel to its gaseous end, this radiant nothingness called flame became to them one of the primary inscrutable, irresolvable things of Nature—an all-devouring element, often of peculiarly divine significance.

The essential nature of flame appears to have been discovered at the beginning of the seventeenth century by the Belgian, Van Helmont. This remarkable man is well known to chemists as one of the acutest and least superstitious of the whole band of alchemists. He was somewhat speculative in the domain of physiology, but in chemistry Van Helmont made discoveries of fundamental importance From our immediate point of view, one of the most important things he did was to sweep away the mystery that had so long attached to the gaseous state of matter. In so far as he distinguished between different gases obtained from different sources, he may be said to have been the first to bring aëriform matter within the range of substantial things that might be submitted to experimental investigation. It was in consequence of this that he was led to the discovery of the nature of flame. I will quote the important passage from his writings.

"But the flame itself, which is nothing but a kindled smoke, being enclosed in a glass in the very instant perisheth into nothing.

"The flame indeed is the kindled and enlightened smoke of a fat exhalation: be it so; but as the flame is such and true fire it is not another matter, being kindled and not yet kindled, neither doth it differ from itself; but that light being united in its centre, hath come upon a fat exhalation which is the same as to be inflamed.

"Let two candles be placed which have first burned awhile, one indeed being lower than the other by a span; but let the other be of a little crooked situation; then let the flame of the lower candle be blown out; whose smoke, as soon as it shall touch the flame of the upper candle, behold the ascending smoke is enlightened, is burnt up into a smoky or sooty gas, and the flame descendeth by the smoke even unto the smoking candle. Surely there is there, the producing of a new being, to wit, of fire, of a flame, or of a connexed light; yet there is not a procreation of some new matter or substance.

"For the fire is a positive artificial death but not a privative one, being more than an accident and less than a substance."

We can best understand the meaning of this somewhat oracular statement by repeating Van Helmont's experiment. We take a bundle of lighted tapers so as to get a large flame, we hold over "in a little crooked situation" another lighted taper, and now blow out the lower flame. We note the ascending column of smoke, and observe that when it touches the upper flame it ignites, and the flame descends several inches through the smoke to the bundle of tapers. Flame therefore, says Van Helmont, is burning smoke; it is not a new substance nor a mere chance occurrence, but the incandescence of a vapour or smoke that already existed.

Van Helmont only recognised in a vague way the important part played by the atmosphere in the phenomenon. This was realised much more perfectly soon afterwards by Hooke, who speaks of "that transient shining body which we call flame", as "nothing but a mixture of air and volatile sulphureous parts of dissoluble or combustible bodies which are acting upon each other whilst they ascend," an action so violent, he says, "that it imparts such a motion or pulse to the diaphanous parts of the air" as was requisite to produce light.

Without entering further into early historical details I may say that it was only towards the end of last century that the essential chemistry of the phenomenon was fully expounded by the great Lavoisier. He showed that, as Hooke had surmised, flame is the region in which combination attended by the evolution of light takes place between the components of a gaseous substance and the oxygen of the air.

The next step in the history of our knowledge of flame brings us to the memorable researches of Humphry Davy, whose name more than that of any other man is associated with this subject. Of Davy's work I shall have more to say presently; but at this moment I will only make one allusion to it, an allusion which will provide us with a proper starting-point this evening. It is interesting to note that Davy's discoveries concerning flame were the consequence and not the cause of the discovery of the miners' safety-lamp. In this case practical application preceded purely scientific discovery.

I need not describe the safety-lamp to you in Nottingham, where it has recently received such important improvements at the hands of Prof. Clowes. When the lamp is placed in an explosive mixture, you know what happens—the explosive mixture burns with a quiet flame within the lamp, but the flame cannot pass through the wire gauze to ignite the mixture outside the lamp. I can demonstrate this by means of this large gas-burner, which is primarily a Bunsen burner, that is, a burner which by means of holes at the base of the tube draws in sufficient air to enable the gas to burn with a practically non-luminous flame. If I turn on the gas and apply a light to the top of the burner, you observe that I get a flash and a small explosion within the tube, but no continuous flame. The fact is that the mixture of gas and air within the tube is highly explosive. Placing a gauze cap over the burner and applying a light, I now get a steady flame. The explosive mixture made in the tube passes through the gauze and is inflamed, or, if you like, exploded; but the explosion cannot pass through the gauze, because the metallic wires withdraw the heat so rapidly that the mixture below it never reaches the temperature of ignition. Above the gauze we have the continuous flame.

"These results are best explained," says Davy, "by considering the nature of the flame of combustible bodies, which in all cases must be considered as the combination of an *explosive mixture* of inflammable gas or vapour and air; for it cannot be regarded as a mere combustion at the surface of contact of the inflammable matter."

Davy, then, regarded flame as being essentially the same as explosion; it was, in fact, a kind of tethered explosion.

Since Davy's time we have learned much about the nature of gaseous explosions, and we now know that such explosions, when fully developed, proceed with enormous rapidity and are of great violence, incapable of arrest by such simple means as we have just used. Still there is not much to correct in what I have said. I think I cannot do better than show you the transition of flame into explosion by an experiment which was first shown by Prof. Dixon in the lecture which he gave at the meeting of the British Association in Manchester in 1887.

The apparatus before you consists simply of a Bunsen burner surmounted by a long glass tube. If I turn the gas on and light it I obtain at the top of the glass tube a steady flame. The mixture ascending the tube can scarcely be called explosive at present, but if I alter the proportions of gas and air suitably it becomes distinctly explosive. Observe what happens when this is the case. The flame can no longer keep at the top of the glass tube; it passes within it, and descends with uniform velocity till at a certain point it flickers and then shoots down almost instantaneously to the bottom. This sequence of events is exhibited in all cases when flame develops into explosion. We are concerned only with the first phase, viz. that of comparatively slow inflammation and a flame, we may say, is a gaseous explosion brought to anchor in the period of incubation.

There is one other point connected with explosion that we must note on account of its important bearing on the chemistry of flame. When we are dealing with explosive mixtures of gas and air, we find practically that the composition of the

[1] An evening discourse to the British Association at the Nottingham meeting, September 15, 1893, by Prof. Arthur Smithells.

mixture may vary considerably and still retain its explosive properties. There is, of course, a certain mixture which presents the greatest explosive power; a further quantity of the combustible gas or of the air will diminish the explosibility, but not entirely destroy it till a large excess is used. With hydrogen, for example, two and a half times the volume of air (which contains exactly the oxygen requisite to combine with the hydrogen and produce water) is the right quantity for the maximum explosive effect, but we still get explosion when we have much more than two and a half times as much air as hydrogen, or when, on the other hand, we have much less. In one case there will be oxygen left uncombined, in the other case hydrogen. I dwell upon this in order that we may be prepared to find the same thing in flames, in order that we may not be surprised to find combustion taking place in mixtures where either gas or air is in excess of the quantity actually required for the purpose of chemical combination. Bearing this in mind, let us revert to the experiment that I have just shown. It consists, you remember, in mixing air with gas before burning it, to such an extent that the flame strikes down the tube. On a close examination we find that this is not quite a correct statement, for when I regulate the air with nicety you see that it is only part of the flame that strikes down the tube. There remains all the while at the top of the tube another part of the flame which is not mobile. With a little care I can adjust the proportion of air and gas so that the part of the flame which is mobile shall move up and down the tube like a piston. All the while you see the pale steady flame at the top of the tube. When in this critical condition a little more air determines the descent of the movable part of the flame, a little less sends it to the top.

Let us now turn to the explanation of this phenomenon. It is clear, in the first place, that coal-gas and air form an explosive mixture long before there is enough air to burn all the gas. For it is only part of the flame that descends the tube, and there is enough gas passing through this part to form a second flame as soon as it reaches the outside air at the top of the tube. There is, as a matter of fact, only about two-thirds as much air entering the tube at the bottom as would be necessary to burn the whole quantity of gas. We see, in the next place, that the explosibility varies greatly according to the proportions of gas and air. For what is the cause of the descending flame? It is simply that we have an explosive mixture in process of inflammation. The inflammation is tending downwards; opposed to it is the movement of the explosive mixture upwards. If the upward movement of the unburned mixture is more rapid than the downward tendency of the inflammation, the flame cannot descend. We can only make it descend by making the downward tendency greater. This we do by adding more air, and making the mixture more explosive. We see that we can balance these two opposite velocities with the greatest nicety by a careful adjustment of the proportions of the explosive mixture.

In order to ascertain what proportion of gas is being burnt in this movable flame, and what is the chemical character of the products there formed, it is necessary to keep the two parts of the flame separate, and to take out some of the gases from the intervening space.

This is very easily done. The flame descends, we have seen, because its rate of inflammation is greater than the rate of ascent of the combustible mixture. If now we can make this rate of ascent more rapid at one part of the tube than it is anywhere else, we may expect to stop the descent of the flame at that point and keep it there. We can do this simply by choking the passage, for just as a river must flow rapidly where its banks are close, so must the stream of gas rush more rapidly where the tube is choked than either below or above, where there is a wide passage. If, then, I replace the plain glass tube by one that has a constriction in one part, and if I cause the inner cone of the flame to descend as before, it stops, as you see, at the constriction, and will remain there any length of time. Its rate of descent is greater than the rate of ascent of the gas where the tube is wide, but not so great as that where it is narrowed by the constriction. We have now got the two cones of flame widely separated. In this state of things we can, if we choose, draw off the gases from the space between the two cones by putting in a bent glass tube and aspirating. We could then analyse these gases and see what has happened in the first cone. (Fig. 1, A.)

I will now show you another method in which the two cones can be separated. It is based on the same principles as the one just used. I have here a two-coned flame burning at the top of a glass tube. I shall let the air supply be liberal, but not quite sufficient to cause the descent of the inner cone. The rate of ascent of the gas is now just a trifle greater than the rate of descent of the flame. If now I retard the rate of ascent of the gas, the balance will be disturbed and the inner cone will descend. I can easily do this by laying an obstacle *along* the stream of gas, for at the end of it there will be no more current than you would find over the stern of a boat anchored in mid stream. I take this obstacle, then, in the form of a glass rod fixed centrally along the current of gas; I push it up until it touches the tip of the inner cone, and then pull it down again. You observe what has happened. The cone has followed the rod into the tube, and remains attached to it. You will notice, too, that the cone is inverted. That is easily understood. It is only at the tip of the rod that the current is slowed down; there only is the rate of ascent of the stream less than the rate of inflammation. The tendency in every other part of the stream is for the cone to go to the top; hence the inversion. (Fig. 1, B.)

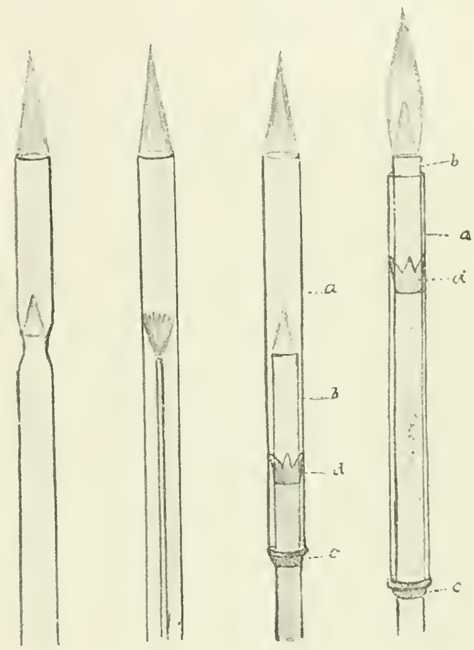

FIG. 1.—Methods of separating the two cones of an air coal-gas flame.

We can get a still more convenient apparatus by a modification of the first method. Instead of choking the bore of the single tube by a constriction, we may use two tubes of different diameter, one sliding within the other. This apparatus is shown in Fig. 1, C; *a* is the wider tube, *b* the narrower one. The two tubes are connected by an india-rubber collar (*c*), and kept steady by the brass guide (*d*). The outer tube can be slid up and down the inner one as desired. If we place this apparatus over a Bunsen burner and turn on the gas, we shall have a tolerably rapid upward current in the inner tube, but as soon as the gas emerges into the wider one its velocity will of course diminish. The consequence is that if we now light the gas and gradually increase the air supply, the inner cone will descend until it reaches the orifice of the narrower tube; but at that point, meeting with the rapid stream, its progress is arrested, and it remains perched on the end of the tube. By sliding the tubes we can thus separate the cones any desired distance, or we can bring their orifices level and restore the original flame. Lastly, we can reverse the experiment, for we can begin with a two-coned flame burning at the protruding end of the narrower tube, and by sliding up the wider tube detach the outer cone and carry it upwards. (Fig. 1, D.)

Having now learnt the relation of flame to explosion, having

discovered that flames have separable regions of combustion, and having armed ourselves with an appliance for dissecting the flame, we may proceed to discuss the main question.

I do not intend this evening to enter seriously into chemical details, but there are one or two simple points to which I must draw your attention. Flame, we see, is a region in which chemical changes are taking place with the evolution of light. It is to be expected, therefore, that the character of a flame, its structure and appearance, will vary according to the chemical changes that give it birth; and we should naturally anticipate that the more complex the chemical changes the more complex would be the flame. The kind of complexity to which I refer is illustrated by the diagram.

Name	Composition	Products: Partial Combustion	Products: Complete Combustion
Hydrogen		water	water
Carbon monoxide	carbon and oxygen	carbon dioxide	carbon dioxide
Carbon		carbon monoxide	carbon dioxide
Cyanogen	carbon and nitrogen	carbon monoxide and nitrogen	carbon dioxide and nitrogen
Hydrogen sulphide	hydrogen & sulphur	(?)	water and sulphur dioxide
Hydrocarbons	hydrogen & carbon	carbon monoxide carbon dioxide hydrogen & water	carbon dioxide and water

In the first column are the names of five combustibles; their chemical composition is stated in the second column. All these substances in burning combine with the oxygen of the air. The case of hydrogen is the simplest. This gas, when it burns, unites with half its volume of oxygen, and forms steam. The process is incapable of any complication. We might predict, therefore, a very simple structure for a hydrogen flame. The same is true for the next gas carbon monoxide, which, although a compound, unites at once with its full supply of oxygen and burns, forming carbon dioxide. The third combustible, carbon, presents a new feature; in burning it can combine with oxygen in two stages, forming in the first instance carbon monoxide, which, as we have just seen, can itself combine with more oxygen to form carbon dioxide. We cannot vaporise carbon and use it as a gas, so that we shall not actually deal with this example. But the next combustible on the list, cyanogen, will serve almost as well, for it is a compound of carbon with nitrogen, and nitrogen is, under ordinary circumstances, practically incombustible. To use cyanogen is thus much the same as to use carbon vapour. We may expect some complexity in the cyanogen flame in consequence of the fact that carbon can burn in two steps. The next combustible, hydrogen sulphide, presents a further degree of complexity. It is composed of two elements, each of which is combustible on its own account. Lastly, we come to the great class of hydrocarbons, which includes all ordinary combustibles, oil, tallow, wax, petroleum, and coal-gas. The carbon and hydrogen are both separately combustible elements, and one of them—carbon—is, as we have seen, combustible in two steps.

We will now consider the problem in its simplest aspect. For this purpose I choose the gas carbon monoxide. I should choose hydrogen were it not for the fact that its flame is almost invisible. We will allow a stream of carbon monoxide to issue from the circular orifice of this glass tube. Lighting the gas we get a blue flame. On examining this flame closely we perceive that it is simply a hollow conical sheath of pretty uniform character. I need scarcely demonstrate that it is hollow, but I may do so in a moment by using Prof. Thorpe's simple device of thrusting a match-head into the centre of the flame—a pin passing through the stick of the match, and its ends resting on the tube. The match-head is now thrust well up inside the flame, and you observe that it remains there sufficiently long without burning, to make it quite clear that there is no combustion within the cone. The conical form of the flame is easily explained. As the stream of gas issues from the tube the outside portions become mixed with the air and burn. The inner layers must successively travel further upwards, like the successive tubes of a telescope, before they can get enough air to burn, and in this way we arrive at the conical form.

There still remains one thing to account for, and that is the luminosity and colour of the flame. The questions here involved are perhaps the most interesting of all, but they are complicated, and I will not say more than a few words about them. The most obvious answer to the question, "Why is the flame luminous?" is to say that the heat developed during the chemical combination raises the product of combustion to a temperature at which it glows—a "blue heat" in the present case. Now if we put a thermometric instrument into the carbonic oxide flame, it does not register at any point as high a temperature as 1500° C., but if we take carbon dioxide and heat it in a tube by external heating to 1500° C. we get no signs of luminosity whatever. On these grounds several eminent investigators have been led to abandon the simple explanation above given, and to say that the luminosity of a carbon monoxide flame must depend not on the heat of chemical combination, but on something in the nature of electrical discharges between the combining substances, which discharges produce the disturbances of the ether perceptible as light. This view seems to be fraught with a fundamental error. The temperature registered by any instrument introduced into a flame is an *average* temperature, uncorrected for losses by conduction. It is not the temperature of the newly-formed gas, but of the mixture of that and the unburned gases. If we had a very small instrument which we could apply to the particles of newly-formed gas, we should undoubtedly find them at a very much higher temperature than any indicated by the ordinary thermometric apparatus, and it is not unlikely that the temperature would be several thousand degrees, approximating indeed to the temperature at which we arrive by calculation from the heat of combustion of the gas and the heat capacity of the product. We cannot say that the flame is luminous from some other cause than simple hotness, for we have no means of seeing whether carbonic acid glows when raised by external heating to a temperature of several thousand degrees.

At the same time one cannot help remarking on the similarity between such a flame as that of carbon monoxide and the appearance presented by an attenuated gas when submitted to the

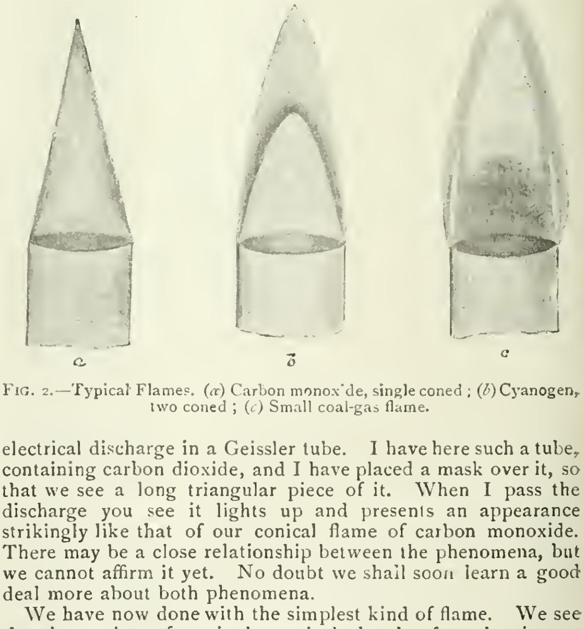

FIG. 2.—Typical Flames. (*a*) Carbon monoxide, single coned; (*b*) Cyanogen, two coned; (*c*) Small coal-gas flame.

electrical discharge in a Geissler tube. I have here such a tube, containing carbon dioxide, and I have placed a mask over it, so that we see a long triangular piece of it. When I pass the discharge you see it lights up and presents an appearance strikingly like that of our conical flame of carbon monoxide. There may be a close relationship between the phenomena, but we cannot affirm it yet. No doubt we shall soon learn a good deal more about both phenomena.

We have now done with the simplest kind of flame. We see that it consists of a single conical sheath of combustion, at every point of which the same chemical change is taking place, and every point of which in consequence has the same appearance.

We pass to the cyanogen flame. This flame is one of remarkable beauty; it consists, as you see, of two distinct parts: one a rose or peach-blossom coloured cone, surrounded by a paler cone, which is bright blue where it is near the inner cone, and shading off to a kind of greenish grey. What is the cause of this double structure? It might be that part of the gas is burning round the orifice, the rest further out in the second cone; but a similarity of the chemical processes in the two parts of the flame is here rendered improbable by the difference in colour. The only satisfactory way of answering the question is to separate the cones, and analyse the gases in the intervening space. This we can easily do in the cone-separating apparatus.

I now form the flame at the top of our cone-separating apparatus, and supply a certain amount of air along with the cyanogen. You observe the rose-coloured cone contracts somewhat. The gas burning there now gets its air supply easily, and has not to wander outwards. If I still further increase the air supply, and make the ascending mixture explosive, you see the inner cone begins to descend into the tube, and passes down until its progress is checked at the narrow tube, where the uprush of gas is more rapid. We have now got the cyanogen flame dissected, and by taking out a sample of the gases from this interconal space and analysing it, we shall find what chemical change has taken place in the inner rose-coloured cone. The analysis shows that what takes place is the combustion of the carbon of the cyanogen to form carbon monoxide almost exclusively; the carbon monoxide then ascends, and when it meets with more oxygen in the outer air, burns in a second cone to form carbon dioxide.

Reverting then to the flame of the pure unmixed gas burning at the top of a tube, we see that the gas and air will interpenetrate. When there is just enough oxygen to burn the gas to carbon monoxide, we get the rose-coloured cone, and outside it, where this carbon monoxide gets more air, we have a second cone. The two-coned structure corresponds then to two chemical stages of combustion.

Now we might go further and anticipate that if we supplied a very large quantity of air to the cyanogen, as in a blowpipe, the two-coned structure would disappear, for the carbon should be burnt up at once to the ultimate product, carbon dioxide. We can easily try this. I will separate the two cones again in our apparatus, and increase the air supply still further. When I do so you observe that the second cone gradually fades away, and now the whole of the combustion is taking place at the end of the inner tube. Though this is so, the flame is not quite a simple cone. It is, as you see, surrounded by a greenish halo. This halo is due, I believe, as Prof. Dixon has suggested, to the fact that the nitrogen of the cyanogen is not, strictly speaking, incombustible. This has been proved by Mr. Crookes in his beautiful air flame, and besides, the greenish halo is frequently noticeable in cases of combustion where oxides of nitrogen are present.

Keeping to our list we ought next to deal with the combustible hydrogen sulphide or sulphuretted hydrogen. This gas, you remember, is composed of two separately combustible elements, each burning in one stage. The flame is, as you might expect, two-coned, but I will not dwell upon this case—partly because it is not yet fully worked out, and partly because any prolonged experimenting with this gas would, I feel sure, be resented even by the most indulgent audience.

I am obliged, therefore, to pass to compounds of carbon and hydrogen, in which there are not only two combustible elements, but one of them, as we have seen, combustible in two chemical stages. Here we have an almost unlimited choice of materials, for we come amongst the combustibles which ordinarily supply us with light. I shall, for the sake of convenience, use coal-gas. This is really a very complex combustible, consisting one half of hydrogen, the other half of at least a dozen different compounds of carbon and hydrogen. But experience has shown that the chemical phenomena attending its combustion are quite of the same character as those to be observed with a single compound of hydrogen and carbon.

It will, I imagine, be scarcely necessary for me to point out the various parts which are to be seen in the flame of a candle or of coal-gas. There is on the diagram (Fig. 2, *c*) before you the picture of a somewhat small coal-gas flame, produced at a circular orifice. It is, of course, enormously enlarged in the diagram. Four distinct parts are to be recognised. First, the central and darkest part; this contains the unburnt gas, just as we saw in the case of the carbon monoxide flame. Perhaps it is wrong to speak of this at all as part of the flame, for it is really a region of no flame. At the base of the flame are two blue strips embracing the lower portion of the flame. This appearance you will understand results from the mode in which we view the flame. The strips are really due to a sheath which goes right round the flame like an uninterrupted calyx. It looks bright where we view it edgewise. When we look through, as in the middle of the diagram, it is very pale indeed. Next we have to notice the bright yellow patch, so bright in the reality as to mask the other parts. Though it looks bright and dense, it is merely a hollow sheath. Lastly, there is surrounding the whole flame a pale mantle of flame of very slight luminosity, and of an almost indescribable tint, which perhaps we may call lilac. These parts are discernible in all ordinary flames. They do not always occupy the same relative space. In the flame given by a good gas-burner the yellow part is made by intention as large as possible; in the flame of a piece of string or a spirit-lamp you will see the outer investing mantle very distinctly developed.

If we are to understand flame, then, we must find an intelligible explanation of the existence of these distinct parts of its anatomy. One important point we can settle at once. An ordinary flame owes its differentiated structure to the slowness with which it gets the oxygen necessary for combustion. If there is an immediate and sufficient supply of air, the characteristic structure disappears. This we can secure by making the stream of gas sufficiently rapid. I have here a steel cylinder containing coal-gas at very high pressure. If I allow the gas to escape slowly, we get a flame in which we should find the ordinary parts. But if now I allow the gas to issue rapidly, the admixture with air is so rapid, and, as you see, we have a pale flame quite undifferentiated in structure. We reach the same result by introducing a strong current of air into an ordinary flame, as in the blast blow-pipe. The flame, you see, is then homogeneous, as in the previous case.

We see then that the structure of an ordinary gas flame is largely dependent upon the slowness with which the gas gets the air necessary for combustion. There is still one other evidence of this. It is obvious that a very small flame will have a much better chance of getting its oxygen quickly than a larger flame. It is, I am sure, within everyone's knowledge that a very tiny gas flame is blue, and, as a matter of fact, we can learn a great deal about flame structure by carefully watching the development of a very small flame. I am going to show you on the screen a series of photographs of actual flames. The photographs have been tinted as faithfully as possible.

The first slide (Fig. 3, *a*) shows a tiny gas flame burning at the end of a glass tube; it consists of a bright blue cone surrounded by a fainter one. Both are quite continuous. By putting in another slide, and using the "dissolving view" arrangement of the lantern, I will show you the effect of turning on the gas. The flame (Fig. 3, *b*) you see is larger, and now is observed a third region in the flame—namely, a patch of bright yellow at the tip. The original cones are still there, but are slightly interrupted at their apices. Turning on more gas, the flame (Fig. 3, *c*) again enlarges, the yellow patch increases in size, and the original cones are further broken into. But you see the yellow patch is indented at points corresponding to the inner cone, which, as it seems, is striving to maintain its integrity. Turning on still more gas, we have now a great preponderance of yellow, the original blue cone is reduced to mere vestiges, and the outer cone forms a faint surrounding to the whole flame (Fig. 3, *d*). This is flame as we ordinarily know it. I wish now to show you another series of changes. We must suppose the gas supply fixed, and the photographs I will show represent the changes which take place in the flame when air is gradually added beforehand to the coal-gas. The supply of coal-gas is, I repeat, the same in all cases. The first change seen is, you will notice, that the yellow patch diminishes in extent (Fig. 3, *e*). If I add more air it diminishes still more, and the inner cone is growing in distinctness (Fig. 3, *f*). If I add a trifle more air, the yellow patch disappears altogether, and we have now complete and distinct inner and outer cones (Fig. 3, *g*). I think you will admit that these two sets of photographs show a close correspondence, and you can see it more plainly if I throw them on to the screen in a group. There is really nothing surprising in this similarity. The smallest gas flame has obviously the best chance of getting air, and when it gets enough it burns in a two-coned flame. The same effect is reached by adding air to the gas before it is burned. If we have a larger gas flame it has, of course, less chance of getting its oxygen rapidly, and we see that in whatever way we starve the flame of oxygen, we lose the simple structure, and come upon the yellow patch.

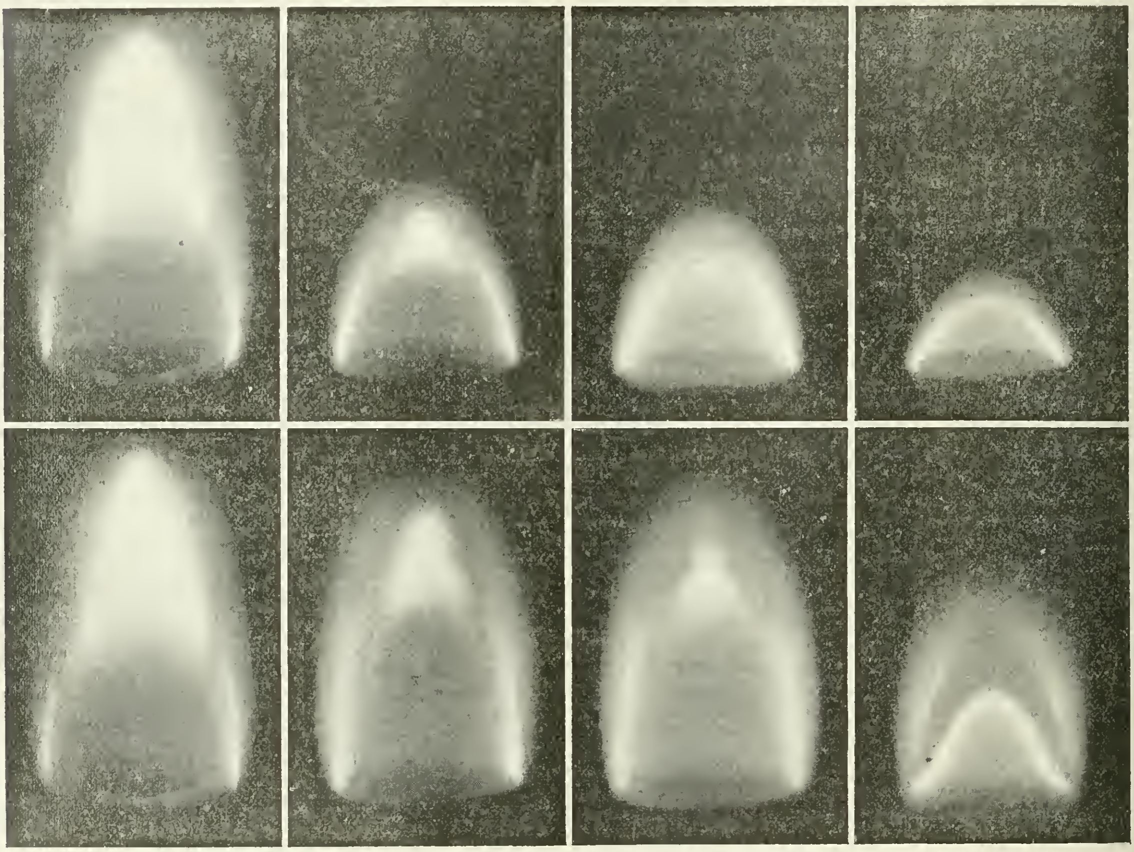
Now, when we come to inquire into the chemical changes occurring in such a flame, we may, I think, feel confident that the chemical actions which determine the existence of the blue cone and the outer cone are the same, whether these cones are complete, as in a small flame, or fragmentary, as in a larger one.

If that is so we can soon make progress, for, as I have shown you, we can easily separate these cones and find what is going on in each. I again use the cone-separating apparatus. First we have an ordinary luminous gas flame at the top of the outer

tube. I pass in air, the flame loses luminosity, and rapidly becomes an ordinary two-coned Bunsen flame. I push the air supply further; the inner cone enters the tube, and descends until it rests on the end of the inner tube. The two cones of a hydrocarbon flame are thus widely separated; we can aspirate a sample of the gases, and see what changes have taken place in the first region of combustion. The result is one that we might await with curiosity, for we have now a competition. There are both carbon and hydrogen to burn, and not enough oxygen to burn both: the question is, which will have the preference? I think I may say that the off-hand opinion of any chemist who has not had his attention drawn specially to this point would be that the hydrogen would easily have the preference. But, as a matter of fact, this question was settled long ago by Dalton, and in the opposite sense, and in the present case analysis would confirm this conclusion. If we analysed

About two-thirds of the carbon is burnt to form carbon monoxide, one-third to form carbon dioxide, whilst rather less than two-thirds of the hydrogen is burnt, and more than one-third remains altogether unburnt. We need not dwell on the details, especially as the analysis of the gases was made after they had cooled. The four gases—carbon monoxide, carbon dioxide, steam, and hydrogen—act upon one, as a matter of fact, while they are cooling down, and the distribution of the oxygen that we find in our analysis of the cold gas is not precisely that which exists in the gases as they just leave the inner cone. We shall only draw a general inference, and it is one that has been recently verified in a very complete manner by Prof. Dixon and his pupils. This inference is simply that the carbon in the inner cone is for the most part burnt to carbon monoxide, and that the hydrogen to a considerable extent is set free. So much then for the inner cone. The outer cone is

d *c* *b* *a*



d *e* *f* *g*

FIG. 3.—*a*, *b*, *c*, *d*, flames with successively increasing quantities of coal-gas. *d*, *e*, *f*, *g*, flames with fixed supply of coal-gas and successively increasing quantities of air.

the gases we should find that all the carbon is burnt in the first cone, whilst a considerable part of the hydrogen passes through unburnt. The change is not quite so simple as these words might apply, as you will see from the actual figures of analysis.

ANALYSIS OF INTER CONAL GASES FROM A COAL GAS AIR FLAME.

Carbon monoxide ...	8·7	17·9 combustible gases.
Hydrogen ...	9·2	
Carbon dioxide ...	4·1	20·1 burnt gases.

		Nitrogen ...	62·0
Amount of air still needed ...	42·9	Oxygen ...	9·0
		Nitrogen ...	33·9

due simply to the burning of the carbon monoxide and hydrogen which escape from the inner cone. When they meet with oxygen in the free air their combustion is completed. We are now in possession of the explanation of the two-coned gas air flame. Applying this to the tiny gas flame to which no air has been previously added, we see that the inner core will be formed where the air has penetrated the gas sufficiently to produce such a gaseous mixture as we had in the lower cone of our separator. The gases coming from this burn further out when they meet with more air, and form a second cone.

The last thing we have to explain in the ordinary gas flame is the production of the yellow luminous patch, which, from the illuminating point of view, is the most important feature of all.

Now I need scarcely remind you that the general opinion is

that this yellow patch in the flame is due to glowing carbon in a solid and very finely-divided state. The very familiar fact that a cold object introduced into the yellow part becomes coated with a black solid deposit, composed almost wholly of solid carbon, confirms this view. That this carbon or soot is solid in the flame, is shown by the fact that it is deposited as a solid even when a highly-heated object is placed in the flame, and there are other proofs—some of them very pretty—which I cannot show for lack of time and of a means of magnifying.

This explanation is due to Davy, and constitutes his most celebrated discovery on the subject of flame. He describes it in the following words:—

"When a wire-gauze safe-lamp is made to burn in a very explosive mixture of coal-gas and air, the light is feeble and of a pale colour, whereas the flame of a current of coal-gas burnt in the atmosphere, as is well known by the phenomena of the gas-lights, is extremely brilliant. . . . In reflecting on the circumstances of the two species of combustion, I was led to imagine that the cause of the superiority of the light of the *stream* of coal-gas might be due to the *decomposition* of a part of the gas towards the interior of the flame where the air was in smallest quantity, and the deposition of solid charcoal which, first by its *ignition*, and afterwards by its *combustion*, increased in a high degree the intensity of the light; and a few experiments soon convinced me that this was the true solution of the problem.

"I held a piece of wire-gauze of about 900 apertures to the square inch over a stream of coal gas issuing from a small pipe, and inflamed the gas above the wire-gauze which was almost in contact with the orifice of the pipe, when it burned with its usual bright light. On raising the wire-gauze so as to cause the gas to be mixed with more air before it inflamed, the light became feebler, and at a certain distance the flame assumed the precise character of that of an explosive mixture burning within the lamp, but though the light was so feeble in this last case, the heat was greater than when the light was much more vivid, and a piece of wire of platinum held in this feeble blue flame became instantly white hot.

"On reversing the experiment by inflaming a stream of coal-gas and passing a piece of wire-gauze gradually from the summit of the flame to the orifice of the pipe, the result was still more instructive, for it was found that the apex of the flame intercepted by the wire gauze afforded no solid charcoal, but in passing it downwards solid charcoal was given off in considerable quantities, and prevented from burning by the cooling agency of the wire-gauze; and at the bottom of the flame, where the gas burnt blue in its immediate contact with the atmosphere, charcoal ceased to be deposited in visible quantities."

Only one attempt has been made to disturb the conclusion here drawn by Davy. In 1868 Prof. Edward Frankland, to whom we are indebted for many important discoveries respecting flame, came to the conclusion that the light-giving agency in flames was not solid carbon, but certain complex vaporous compounds of carbon and hydrogen. I regret very much that time will not admit of my detailing the evidence in favour of this view, or the counter evidence by means of which most chemists have been persuaded that Davy's explanation was, after all, the correct one. It is, however, right to remark that Prof. Frankland not only adheres to his own view, but promises to adduce further evidence in its favour.

Let us for the present, at any rate, stick to the opinion of the majority, and admit that the bright light of ordinary flames is due to incandescent particles of solid carbon. The next question is, How does this carbon become separated?

This question is dealt with by Davy, but in language of some ambiguity. He says, "I was led to imagine" . . . . that it "might be due to the *decomposition* of a part of the gas towards the interior of the flame where the air was in smallest quantity, and the deposition of solid charcoal which first by its *ignition*, and afterwards by its *combustion* increased in a high degree the intensity of the light."

Whatever these words may have been intended to mean, or whatever interpretation is the fair one, it is certain that Davy's explanation was soon presented as if it implied lack of air to be the chief cause of carbon separation. As there was a large quantity of hydrocarbon, and only a small amount of oxygen in the central parts of flame, the hydrogen, it was said, being the more inflammable element, will seize upon this oxygen and leave the carbon uncombined. The fact that this version was given by Faraday lends some countenance to the belief that it was a fair representation of Davy's view.

Now this doctrine was really incompatible with facts known, though apparently not widely known, at the time. I have already referred to the fact that Dalton at the beginning of the century showed that when a hydrocarbon is exploded with a supply of oxygen insufficient to burn both the hydrogen and the carbon, it is the carbon, and not the hydrogen, which has the preference. If, therefore, we follow Davy in regarding flame as a tethered explosion, we cannot explain the separation of carbon as being due to the preferential combustion of the hydrogen. This fact was clearly pointed out by Kersten in 1861, but notwithstanding this, and other investigations tending to the same conclusion, the old view has somehow kept its ground down to the present day.

We must now turn to the alternative explanation. It is supplied by the words, and I think, by the intention, of Davy. He says that the carbon separation might be due to the *decomposition* of the gas towards the interior of the flame. If this decomposition be not due to chemical action, it must be due to heat; and certain it is that hydrocarbons when strongly heated do decompose, and do deposit carbon. Here is a result of this action occurring on the large scale. This gas-carbon, as it is called, is deposited in gas-retorts owing to the action of intense heat on the hydrocarbons of the gas.

In another place Davy says: "I have shown in the paper referred to in the introduction, that the light of common flames depends almost entirely upon the deposition, ignition, and combustion of solid charcoal, but to produce this deposition from gaseous substances demands a high temperature."

This explanation of carbon separation in flames seems perfectly adequate and free from objection. There is, as we have seen, surrounding all ordinary hydrocarbon flames a shell of almost non-luminous combustion. The gas which passes upwards within this shell must be highly heated, and in the absence of air will be decomposed so as to deposit solid carbon. This carbon is intensely heated, and glows, and as it reaches the air will burn to form carbon dioxide. The fact that the upper parts of flame are the most luminous in itself indicates that the more we roast the gas the more do we separate the carbon; and there are other proofs, which I cannot stop to explain.

We have now got pretty well to the end of the explanation of the structure of ordinary luminous flames, and I will show you an experiment which epitomises the explanations that have been given.

We turn once more to the cone-separating apparatus, and use as fuel a substance particularly rich in carbon. This substance, benzene, is a liquid, so I shall have to vaporise it by means of a current of air. When I apply a light to this current of air strongly impregnated with benzene, we get, as you see, a very bright flame. This flame exhibits the usual structure. This is one extreme. Now I will reduce the amount of benzene vapour very rapidly without altering the air, and we shall get the other extreme, that is, a scarcely luminous flame consisting of one single cone. The whole of the combustion is now taking place in a single cone of flame. If I still further reduce the benzene, this flame enlarges slightly and becomes paler. There is now excess of air. A little less benzene still, and you see the flame rises from its perch and disappears; we have got past the limits within which combustion is possible. Let us next move in the other direction, and gradually increase the supply of benzene to the single cone. It becomes smaller and brighter as we proceed up to a certain point. At length we have evidently got more benzene than there is air to burn, and now appears the second cone at the top of the tube. By sliding the tubes we can unite the flame and make a Bunsen flame. Separating the cones again, let us add still more benzene. The result is very remarkable. The two cones remain intact, but stretching between them are thin luminous streaks of glowing carbon. The excess of benzene is being decomposed by the heat, so that the carbon separates and glows. The more benzene I add the broader do these streaks become, until eventually the inner cone ascends, the luminous streaks coalesce, and we have the ordinary luminous hydrocarbon flame.

I have now put before you the considerations and methods which will serve, I believe, for the elucidation of all problems of flame *structure*. I am not aware, at any rate, of any flame which does not accord with the general principles which I have explained to you.

There are many other flame problems besides that which relate to mere structure. Of these one of the most interesting concerns the colouration of flame. I will refer to it for a moment

only to show how closely that question is connected with the points we have been discussing. I have here a gas flame to which I feed air until its yellow luminosity has disappeared. If I add to the air supply the fine spray of a dissolved copper salt, the flame assumes a green tint characteristic of the metal. This green tint seems to belong to the whole flame, but if we dissect it by the apparatus already so often used, we find that the green tint is developed only in the outer cone. It is due, in fact, to oxide of copper, which can only exist on the outside of the flame. Similar peculiarities are noticed with some other coloured flames, and it is hoped that their study, which leads us into the domain of spectrum analysis, will yield some interesting information on points which are at present very obscure.

I have directed your attention this evening to terrestrial flames of small dimensions, but in conclusion I should like to remind you that at one time there were probably quite other flames upon this earth. The globe we inhabit is in the process of cooling and of oxidation; at one time we believe, in fact we know, that it was incandescent. If we take a chemical retrospect and imagine as we recede in time our present cool earth becoming hotter, we may follow out some interesting changes. We should soon reach a temperature too high for the persistence of liquid water; our oceans would be evaporated and surround the globe as an envelope of steam. In remoter times and at higher temperatures this steam could not exist even as steam, but would be dissociated into hydrogen and oxygen. At that time, too, many of the elements now existing as oxides in the solid crust of the earth would be floating in a gaseous state in the vast atmosphere. Let us stop our retrospect at this point, and look towards the present with a cooling earth. At a certain point chemical combination must have begun in the fringe of the ancient atmosphere, and it must have been the scene of colossal chemical activities, the hydrogen and vaporous metals flashing into their oxides. On gravitating to hotter regions, these combinations may have been again undone, the elements sent again into circulation. How long such a period may have lasted we need scarcely stop to ask. If the retrospect is reasonable, it is enough. It is interesting to think how such an earth as we have pictured must have resembled the sun as we know it at the present day.

There was formerly a chemical theory of the sun, which ascribed both its heat and light to the act of chemical combination. That theory has long since been refuted and discarded, and with it ordinary laboratory chemistry banished from that luminary as altogether unsuited to its high temperature. There is cause, I think, to ask if this is quite warrantable. We know extremely little of chemistry at high temperatures, but if the sun could be shown to have its reasonable share of oxygen, we might well ask if its surface phenomena were not largely ascribable to ordinary chemical activities and of the nature of flames. It is certainly remarkable, when we consider the unity of plan in which heavenly bodies are seen more and more to move and have their being, that the sun should not exhibit the possession of its fair share of that element—oxygen—which has ruled the chemistry of the earth throughout all geological time and long precedent ages of its evolution. But this is ground which the terrestrial chemist must tread with care. He still has many unsolved problems lurking in the flame of a common candle, and flame, wherever we find it, is still a mystery.

"The power of *Fire* or *Flame*," says Carlyle, "which we designate by some trivial chemical name, thereby hiding from ourselves the essential character of wonder that dwells in it as in all things was with the old northmen Loke, a most swift subtle *Demon* of the brood of the Jötuns. The savages of the Landrones Islands too (say some Spanish voyagers) thought Fire, which they never had seen before, was a devil or god, that bit you sharply when you touched it, and that lived upon dry wood. From us, too," adds Carlyle, "no Chemistry, if it had not stupidity to help it, would hide that Flame is a wonder."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—On Monday, the 20th inst., Prof. E. B. Poulton, the President of the Ashmolean Society, gave a *conversazione* in the University Museum, which was numerously attended by members of the city and University, who were specially invited to meet the Local Executive Committee of the British Association. The features of the entertainment were: an interesting lecture on features in the past history of science in Oxford, by Mr. Falconer Madan; physical experiments, by Prof. Clifton and Mr. J. Walker; exhibits of various entomological specimens from the Hope Collection; glass-blowing, by Herr Zitzmann; living animals and museum preparations, by Dr. Benham and Mr. Goodrich; physiological exhibits, by Messrs. Pembrey, Gordon, and Howard; and many other exhibitions which cannot be noticed for want of space.

The Junior Scientific Club, whose proceedings have been hitherto published in a somewhat haphazard manner, have decided to issue a series of fortnightly numbers, each of which contains an account of the papers read at the previous meeting. The first of these was published on the 17th inst., and is in all respects a credit to its editor. It contains, besides abstracts of papers read by Messrs. M. H. Gordon, S. A. Simon, and W. J. Waterhouse, a syllabus of all the papers read before the club during the past year, an obituary, and notes on the distinctions gained during the past year, by present and former members of the club.

At a meeting of Convocation held on Tuesday last, Dr. Arthur Thomson, University Reader in Human Anatomy, was appointed Professor of Human Anatomy.

Cambridge.—Mr. M. R. James, of King's College, has been appointed Director of the Fitzwilliam Museum in succession to Prof. Middleton.

An election to an Isaac Newton studentship in astronomy, astronomical physics, and physical optics, will be held in the Lent Term 1894. The candidates must be B.A.s and under the age of twenty-five. The studentship is worth £200 a year for three years. Applications to be sent to the Vice-Chancellor by January 26, 1894.

A syndicate has been appointed for the purpose of obtaining specifications and tenders for the erection of the Sedgwick Memorial Museum of Geology, in accordance with the plan of Mr. T. G. Jackson.

An influential deputation waited upon the Chancellor of the Exchequer on Tuesday in order to place before him the necessity for continuing, and, if possible, increasing, the Parliamentary grant of £15,000, which was conceded to the University Colleges in 1889. Sir W. Harcourt said that though he was prepared to recommend the renewal of the grant, the present condition of public finances would not permit him to propose its increase.

SCIENTIFIC SERIALS.

American Journal of Science, November.—On New England and the Upper Mississippi basin in the glacial period, by James D. Dana. During the recent discussions concerning the unity or otherwise of the glacial epoch in North America, it has appeared that workers in the central and western portions have mostly advocated two glacial epochs, while New England geologists have been the chief advocates of unity. The author has not found any facts in New England geology that require for their explanation an appeal to two glacial epochs, but has found an explanation of the appearances which have led western geologists to that opinion. The cause of this sectional divergence is mainly meteorological. Even at the present time, the precipitation in the east is far above that of the west, and in the glacial epoch the difference must have been still greater, owing to the greater elevation of the east. The conditions of the ice-sheet in the interior being near the critical point, a small meteorological change, if long continued, might carry off the ice for scores or hundreds of miles from a southern limit, while the eastern border was all the time gaining in ice, or was making only a short retreat.—On the use of the name "Catskill," by John J. Stevenson. Mr. Darton's suggestion that the term Catskill should be applied to the whole of the Upper Devonian period is inappropriate, since Catskill has been shown to belong to an epoch only, whereas "Chemung" carries with it the conception of those physical and biological characteristics which mark the great closing period of the Devonian.—The finite elastic stress-strain function, by G. F. Becker. This is an investigation of finite stress and strain from a kinematical point of view, and of the function which satisfies the kinematical conditions consistent with the definition of an isotropic solid. The bearing of the theory upon finite sonorous vibrations is compared with the corresponding deductions from Hooke's incomplete law.—A larval form of Triarthrus, by C. E. Beecher. Since the discovery of antennæ and other appendages of this

trilobite by Mr. W. D. Matthew, it has been possible, with the new material supplied to the Yale Museum, to trace its development back to the earlier stages. Larval specimens have been found in which the thorax is undeveloped and the cephalon predominates, while the other parts are not clearly differentiated. The larva is ovate in outline. The frontal margin is marked by a convex fold of the test. The axis is annulated. Near the lateral anterior margins are two slight elevations which may represent the palpebral lobes of the eyes.

American Journal of Mathematics, vol. xv. No. 4.—On toroidal functions, by A. B. Basset (pp. 287–302). The theory of these functions was first investigated by Prof. W. M. Hicks, in his discussion of the motion of circular vortex rings (*Phil. Trans.* 1881). The author considers that Prof. Hicks presented the subject in a somewhat complicated form, and the object of his own communication is to develop the subject, and to correct errors which he attributes to Prof. Hicks. The memoir appears to be on the lines of a communication Mr. Basset made to the London Mathematical Society (April 13, 1893).—Simple groups as far as order 660, by F. N. Cole (pp. 303–315). This is a continuation of a paper in vol. xiv., in which it was shown that the orders of simple groups between the limits 200 and 500 are restricted to two possibilities, 360 and 432. In the present memoir the order 432 is shown to be inadmissible, and the order 360 to furnish only one type of a simple group. Two other simple groups are shown to present themselves, of orders 504 and 660 respectively. The order 504 "seems hardly to have been recognised hitherto." It was a singular fact, pointed out at the November meeting of the London Mathematical Society, that this memoir anticipated some results in Prof. W. Burnside's notes on the theory of groups of finite order. The latter had evidently arrived at his result quite independently of Dr. Cole.—On the expansion of functions in infinite series, by W. H. Echols (pp. 316–320).—The elliptic inequalities in the lunar theory, by E. W. Brown (pp. 321–338). This is a resumption of the author's paper from p. 263.—On the multiplication of semi-convergent series, by F. Cajori (pp. 339–343). The writer's object is to extend results given by A. Voss, in the *Math. Ann.* (vol. xxiv. p. 44).—On certain ruled surfaces of the fourth order, by T. F. Holgate (pp. 344–386). An introductory section is historical, and refers to previous memoirs on the subject. The author considers those species of the surface of the fourth order which may be generated by two projective sheaves of planes of the second order. These admit of a trinodal quartic section, and are consequently of deficiency zero. The volume concludes with a note on the so-called quotient G/H in the theory of groups by Prof. Cayley, (pp 387–8), and the index of contents.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, November 10.—Prof. A. W. Rücker, F.R.S., President, in the chair.—A paper on the separation of three liquids by fractional distillation, by Prof. F. R. Barrell, G. L. Thomas, and Prof. Sydney Young, F.R.S., was read by Prof. Young. Accepting the results obtained by F. D. Brown in his experiments on the variation in the composition of the distillate from a mixture of two liquids, viz. that the relative quantities of the two substances in the vapour at any instant are proportional to the weights of the substances in the still, multiplied by the ratio of their vapour pressures, the authors write Brown's equation in the form $\frac{d\xi}{d\eta} = c\frac{\xi}{\eta}$, where ξ and η are the weights of the two liquids in the still, and c the ratio of their vapour pressures. Taking c as constant, the above equation is integrated, and from the resulting expressions curves are plotted showing the changes in composition that take place during the distillation. Assuming that a similar law holds for three liquids, A, B, and C, viz. $\frac{1}{a}\frac{d\xi}{\xi} = \frac{1}{b}\frac{d\eta}{\eta} = \frac{1}{c}\frac{d\zeta}{\zeta}$, the composition of the distillate at any instant is calculated. Taking $a = 4$, $b = 2$, and $c = 1$ (numbers nearly proportional to the vapour pressures of methyl, ethyl, and propyl acetates), numerous curves are plotted showing the progress of the separation at various stages of fractionation. These curves show distinctly that although fractions containing large proportions of the liquids A and C, of lowest and highest boiling points respectively, can be easily separated, the middle substance, B, is much more difficult to obtain in a state of purity. Consideration of these curves led the authors to see that by carrying out the fractionation in a particular way, it was possible to separate the mixture into two portions, one containing only A and B, and the other B and C. These mixtures of two liquids could then be fractionated in the usual manner. This process was carried out on a mixture of methyl, ethyl, and propyl acetates, the results of which are given in considerable detail in the paper. The remarkable agreement between the densities of the ethyl acetates obtained respectively from the mixtures A and B, and B and C, as well as the fact that the densities of the separated liquids were the same as before the mixing, show conclusively that the method employed was highly successful. Prof. Ramsay said the paper was a most valuable one, and would be a great aid to chemists. Distillations were usually carried out by mere "rule-of-thumb," with the result that absolutely pure liquids could rarely be obtained. The President inquired whether curves representing the progress of distillation could be constructed from the very complete experiments made, and so test the assumed law. Prof. Young thought this not possible from the numbers obtained. To test the law in this way would be very laborious.—A note on the generalisations of Van der Waals regarding "corresponding" temperatures, pressures, and volumes, was read by Prof. S. Young. In November 1891 the author read a paper on the same subject (*Phil. Mag.* February 1892), and gave the critical molecular volumes of some twelve substances as calculated by M. Mathias. Since then a few small errors have been found in the calculation, and the authors' corrected values are now given. The vapour pressures, molecular volumes and critical constants of ten esters (methyl formate, acetate, propionate, butyrate, and isobutyrate, ethyl formate, acetate and propionate, and propyle formate and acetate) have recently been determined (Trans. Chem. Soc. lxiii. p. 1191). In the present paper the absolute temperatures and volumes of the twelve substances are given in terms of their critical constants, and tables given showing, respectively, the ratios of boiling points (abs. temps.) at corresponding pressures, to absolute critical temperatures; the ratios of volumes of liquid at corresponding pressures to the critical volumes, and ratios of volumes of saturated vapours at corresponding pressures to critical volumes, for the halogen derivatives of benzene, carbon tetrachloride, stannic chloride, ether; methyl, ethyl, and propyl alcohols, and acetic acid; and the extreme values for the ten esters previously mentioned. Whilst showing fair agreement with each other, the differences between them exceed errors of experiment. The ratios also indicate that the substances can be arranged in four groups, thus tending to show that molecular weight and chemical constitution have some influence on the results. The differences found would probably result from the presence of complex molecules, such as are known to exist in acetic acid. If Van der Waals's generalisations were strictly true, the ratio $\frac{pv}{T}$ at the critical point should be constant for all substances, as also the ratio $\frac{D}{D'}$ of the actual to the theoretical density (for a perfect gas) at the critical point. On comparing these quantities only a rough approximation is found, but the grouping of the compounds is again well marked. Prof. Ramsay was not sure that the existence of complexes would alter the molecular volume in the liquid state, for liquids seem very compact. Experiments on the surface energy of liquids had proved that complex molecules do exist in the alcohols and acetic acid. Dr. Young's conclusions were therefore confirmed by experiments of an entirely different nature. Prof. Herschel was gratified to see Van der Waals's theory so well borne out in liquids, and hoped to see it extended to solids. The recent researches of Prof. Robert Austen on alloys seemed to point in this direction. Mr. Rogers said molecular complexes do exert an influence on the properties of substances, as had been shown by Prof. Thorpe's viscosity experiments. Van der Waals's generalisations should therefore be looked at from a chemical as well as a physical point of view. The President thought the number brought forward showed fair agreements, especially when it was remembered that Van der Waals took no account of complex molecules. Contrary to Prof. Ramsay, he would rather expect aggregation to affect the molecular volumes in the liquid state, for only about one-fifth the space was supposed to be occupied by matter. On the other hand, the relatively

small contraction of liquids on cooling did not support this view.—An instrument for drawing conic sections was exhibited and described by Mr. J. Gillett. This consists of a spindle inclined to a plane board, and a tube fixed to the spindle at an angle. A pencil which passes through the tube traces out a cone in space as the spindle is turned, and on sliding the pencil through the tube, so as to keep its point against the plane, the point traces out a conic, the section of the cone made by the plane of the board. A circle, ellipse, parabola, or hyperbola, can be drawn according to the inclination of the spindle to the board. Prof. Henrici said a similar instrument had been described in an Arabian manuscript a thousand years old, and has been independently re invented by both a German and an Italian mathematician. He thought the fact of the angle between the spindle and the tube in Mr. Gillett's instrument not being adjustable was a disadvantage. Mr. Inwards and Prof. Herschell also took part in the discussion, to which Mr. Gillett replied.

Geological Society, November 8.—W. H. Hudleston, F.R.S., President, in the chair.—The following communications were read:—The geology of Bathurst, New South Wales, by W. J. Clunies Ross. After sketching the physiography of the Bathurst district, the author described in detail its stratigraphy. The oldest sedimentary rocks are Silurian, but the floor on which they rest is unknown, and the author stated that it was probably fused up and incorporated in the granite, which is described in the paper. The Silurian rocks may have been folded before the granite was erupted; in any case, the granite produced a zone of contact-metamorphism, whilst almost all the Silurian rocks may be considered to be examples of regional metamorphism, though the agents producing the metamorphism were least active to the east of Bathurst, where the Silurian limestones are very little altered. An anticlinal was probably produced at the time of the granitic intrusion. After a time there was subsidence, but at first it need not have been very extensive, since the Devonian conglomerates, sandstones, and shelly limestones were probably deposited in a comparatively shallow sea. They contain *Lepidodendron australe*. At Rydal they abut against the uplifted Silurian rocks of the Bathurst area. At the end of Devonian times there appears to have been a long interval, during which both Silurian and Devonian rocks were greatly denuded, and the granite exposed in places. The Upper Carboniferous and Permian rocks were deposited in the Lithgow district, but it is doubtful if they ever extended to Bathurst. There is nothing to show what happened in this region during Mesozoic and early Tertiary times. The Hawkesbury Sandstone (probably Triassic) may have approached nearer to Bathurst than it does now. In late Tertiary times stream-deposits were formed on the granitic rocks, and afterwards covered with thick basaltic lava-flows, which have since undergone much denudation. A discussion followed, in which the President, the Rev. H. H. Winwood, and Mr. J. E. Marr took part.—The geology of Matto Grosso (particularly of the region drained by the Upper Paraguay), by Dr. J. W. Evans. The district includes a portion of the Brazilian hill-country, and also of the low-lying plains to the south-west The rocks principally dealt with are unfossiliferous, and of unknown age, except that they appear to be older than the Devonian. They may be classified as follows:—(5) Matto Shales (relations not shown); (4) Rizama Sandstone (perhaps some unconformity); (3) Curumbá and Arara Limestones (very marked unconformity); (2) Cuyabá Slates (strong unconformity); (1) ancient crystalline rocks. The Devonian and later rocks were briefly described. The President, Mr. Spencer Moore, fellow-traveller with Dr. Evans in Matto Grosso, Mr. H. Bauerman, and Mr. R. D. Oldham spoke on the subject of the paper.—Notes on the occurrence of mammoth-remains in the Yukon district of Canada and in Alaska, by Dr. George M. Dawson, C.M.G., F.R.S. In this paper various recorded occurrences of mammoth-remains were noted and discussed. The remains are abundant in, if not strictly confined to, the limits of a great unglaciated area in the north western part of the North American continent; whilst within the area which was covered by the great ice-mass which the author has described as the Cordilleran glacier, remains of the mammoth are either entirely wanting or are very scarce. At the time of the existence of the mammoth the North American and Asiatic land was continuous; for an elevation of the land sufficient to enable the mammoth to reach those islands of the Bering Sea, where these bones have been found, would result in the obliteration of Bering Straits. The bones occur, along the northern coast of Alaska, in a layer of clay resting on the somewhat impure "ground-ice formation" which gives indications of stratification; and above the clay is a peaty layer. The author considered this "ground-ice" was formed as a deposit when more continental conditions prevailed, by snow-fall on a region without the slopes necessary to produce moving glaciers. The mammoth may be supposed to have passed between Asia and America at this time. At a later date, when Bering Straits were opened and the perennial accumulation of snow ceased on the lowlands, the clay was probably carried down from the highlands and deposited during the overflow of rivers. Over this land the mammoth roamed, and wherever local areas of decay of ice arose bogs would be produced which served as veritable sink traps. The author considered it probable that the accumulation of "ground-ice" was coincident with the second (and latest) epoch of maximum glaciation, which was followed by an important subsidence in British Columbia. In the discussion of the paper, Sir Henry Howorth remarked upon the long and careful survey of North-West America which has been made by the author, and upon the value of the conclusions which he has come to: firstly, in regard to the absence of ancient glaciation in Alaska and its borders; secondly, in regard to the existence of a great glacier in the Cordilleras, whose products are quite independent of and have nothing to do with the Laurentian drift; and thirdly, in regard to the distribution of the mammoth. It was a new fact to him, and one of great importance, that mammoth-remains had occurred in Unalashka and the Pribilof Islands in Bering Straits, proving that in the Mammoth age there was a land bridge here, as many inquirers had argued. It would be very interesting to have the western frontier defined where the mammoth-remains cease to be found. It would be very interesting to know how far south on the west of the Cordilleras the true mammoth, as distinguished from *Elephas Columbi*, has occurred. Regarding one conclusion of Dr. Dawson's, Sir Henry could not agree with him, namely, about the age of the strata of ice sometimes found under the mammoth-beds in Alaska as they have been found in Siberia. The speaker was of opinion that this ice had accumulated since the beds were laid down, and was not there when the mammoth roamed about in the forests where he and his companions lived. Humus and soil cannot accumulate upon ice except as a moraine, and there are no traces of moraines or of great surface-glaciation in Alaska and Siberia. Nor could either the flora or fauna of the memmoth age have survived conditions consistent with the accumulation of these beds of ice almost immediately below the surface, or consistent with their presence there. The speaker considered that these beds were due to the filtration of water in the summer down to the point where there is a stratum of frozen soil, through which it cannot pass and where it consequently accumulates, freezes, raises the ground, and in the next season grows by the same process until a thick bed of ice has been formed. The evidence goes to show that the present is the coldest period known in recent geological times in Siberia and Alaska, and that the period of the mammoth and its companions was followed and not preceded by an Arctic climate where its remains occur. Dr. H. Woodward remarked that the most interesting point in Dr. Dawson's paper was the mention of the remains of mammoth on the Aleutian Islands, proving that this was the old high road for this and other mammals from Asia into North America in Pleistocene times.

Linnean Society, November 2.—Prof. Stewart, President, in the chair.—The secretary having read a list of the donations to the library since the last meeting, the President moved that the thanks of the society be given to the donors and to Lady Arthur Russell for the valuable collection of engraved portraits of naturalists which she has been so good as to present to the society in the name of her husband, the late Lord Arthur Russell, a motion which was passed unanimously. The President then referred to the improvement which had been carried out during the recess in the society's apartments by the introduction of the electric light, for which they were indebted to the liberality of the treasurer, Mr. Crisp, who on former occasions had shown himself so generous a benefactor, and moved that the hearty thanks of the society be given to Mr. Crisp for his munificent present. The resolution was carried by acclamation. Referring to the deaths of Fellows of the society which had occurred since the last meeting, the President alluded especially to the Rev. Leonard Blomefield, whose connection with the society, extending over seventy years, had recently been made the subject

of a congratulatory address, to Mr. F. Pascoe, the distinguished entomologist, and to Mr. George Brook, whose lamented decease had caused the vacancy in the Council which they now had to fill. The ballot having then been taken for the election of a new councillor in the place of Mr. George Brook, deceased, Mr. Henry Seebohm was declared to have been elected.—Mr. George Murray exhibited and made remarks on a series of seaweeds mounted on lantern slides, some of which were new to Great Britain. He also showed some specially prepared tins which were recommended for collecting purposes, but which in the opinion of some present would be likely to become speedily useless from oxidisation.—Mr. Holmes showed some new British marine algæ, and made remarks on their affinities.—Dr. Prior exhibited the fully developed fruit of *Pyrus japonica* from Rogate, Sussex, seldom seen, although the plant is common, and alluded to its use as a conserve if it could be obtained in sufficient quantity.—Mr. Spencer Moore read a paper on the phanerogamic botany of an expedition to Mato Grosso, upon which he acted as botanist. Starting from Cuyaba, the expedition first visited the Chapada Plateau, to the east of that city, where many plants were collected. Thence a journey was made to the new settlement of Santa Cruz, on the Paraguay, about half-way between Villa Maria and Diamantino. The flora here is of mixed character, nearly 37 per cent. of the plants being common to tropical South America, upwards of 27 per cent. occurring in the N. Brazil Guiana province of Engler, with 20·5 per cent common to that province and the S. Brazilian, and only 13 per cent. of S. Brazilian types. From Santa Cruz a party penetrated through the primeval forest lying to the north, and reached the Serra de Sapitrapuan. The forest flora is markedly Amazonian in character, nearly 50 per cent. of the plants being natives of Amazonia or of the neighbouring countries within the N. Brazil Guiana province, or related thereto, while the proportion of species common to tropical America falls to rather more than 28 per cent. the S. Brazilian element being present only to the extent of 9·5 per cent. Returning to Santa Cruz, the Rio Bracisto was partly explored, and the Paraguay ascended to the neighbourhood of Diamentino. The party then came down the Paraguay to the Corumba, where many plants of interest were found. The expedition was partly disbanded at Asuncion. Among the Amazonian plants found at Santa Cruz, or in the forest, may be mentioned *Randia Ruiziana*, *Bertiera guianensis*, the Loranthad *Oryctanthes ruficaulis*, *Cattleya superba*, *Epidendrum imatophyllum*, *Rodriguezia secunda*, &c. The collections comprise close upon 700 species, of which rather more than 200 were considered to be new, and referable to eight new genera. The southward extension of the Amazonian flora to a latitude well within the Paraguay River system was regarded as a noteworthy feature.—On behalf of Mr. G. M. Thomson, of Dunedin, N.Z., Mr. W. Percy Sladen read a paper on a new freshwater Schizopod from Tasmania, illustrating his remarks with graphic sketches on the blackboard to indicate its affinities and differences.

Entomological Society, November 8. — Henry John Elwes, President, in the chair.—Mr. F. Merrifield exhibited some low-temperature forms of *Vanessa atalanta*, artificially produced, which showed a great reduction in the area of the scarlet bands on the wings, and a great increase in the area of the white and bluish markings.—Prof. E. B. Poulton, F.R.S. described and illustrated, by means of a map, a simple method for showing the geographical distribution of insects in collections. Below the name-label of the genus, and of each species, were placed coloured slips of such a size as to be distinctly visible at a distance, and the colours, with one exception, corresponded with those made use of in the map at the beginning of vol. i. of Dr. A. R. Wallace's "Geographical Distribution of Animals." The exception referred to was the Palæarctic region, which was coloured blue, instead of pale brown as in the original. Framed maps of the same kind, and coloured in the same way as the one he exhibited, were to be placed in museums, so as to be readily seen from various groups of cabinets. In these maps the names of the regions, and numbers of the sub-regions, were distinctly printed, so that they could be read at a considerable distance. Prof. Poulton added that the method he had described was being gradually introduced into the Hope Collections at Oxford. Mr. McLachlan, F.R.S., stated that a somewhat similar plan to that described for showing the geographical distribution of insects has been adopted in the Brussels Museum by M. Preudhomme de Borre. Mr. W. F. H. Blandford, Dr. D. Sharp, F.R.S., Mr. C. J. Gahan, Mr. C. O. Waterhouse, Mr. Osbert Salvin, F.R.S., Prof. Poulton, and the President continued the discussion.—Dr. Sharp read the following extract from Dr. Livingstone's "Narrative of an Expedition to the Zambesi," and stated that he was indebted to Mr. Gahan for calling his attention to it:—"We tried to sleep one rainy night in a native hut, but could not because of attacks by the fighting battalions of a very small species of *Formica*, not more than one-sixteenth of an inch in length. It soon became obvious that they were under regular discipline, and even attempting to carry out the skilful plans and stratagem of some eminent leader. Our hands and necks were the first objects of attack. Large bodies of these little pests were massed in silence round the point to be assaulted. We could hear the sharp, shrill word of command two or three times repeated, though until then we had not believed in the vocal power of an ant; the instant after we felt the storming hosts over head and neck."—Prof. Poulton read a paper entitled "On the sexes of larvæ emerging from the successively laid eggs of *Smerinthus populi*." Mr. Merrifield, Dr. Sharp, and the President took part in the discussion which ensued.—Mr. W. L. Distant communicated a paper entitled "On the Homopterous genus *Pyrops*, with descriptions of two new species."—The President read a paper, written by himself and Mr. J. Edwards, entitled "A revision of the genus *Œneis*," which he characterised as the most cold-loving genus of butterflies. He also exhibited his complete collection of species of this genus. A long discussion ensued, in which Prof. Poulton, Mr. McLachlan, Mr. Salvin, Mr. Bethune-Baker, the Rev. Dr. Walker, Mr. Kirby, Mr. Merrifield, Mr. Barrett, Mr. Blandford, Dr. Sharp, and Mr. Jacoby took part.

Zoological Society, November 7.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—Mr. Sclater read some notes on the most interesting animals he had seen during a recent visit to the Zoological Gardens of Stuttgart, Frankfort, and Cologne.—An extract was read from a letter addressed to the Secretary by Mr. J. G. Millais, relating his endeavours to obtain specimens of the White Rhinoceros (*Rhinoceros simus*) in Mashonaland.—A communication was read from Babu Ram Bramha Sányál, describing a hybrid monkey of the genus *Semnopithecus*, born in the Zoological Gardens, Calcutta.—Mr. Tegetmeier exhibited a specimen of a hybrid grouse between the blackgame (*Tetrao tetrix*) and the red grouse (*Lagopus scoticus*).—Mr. Boulenger read a paper on a Nothosaurian reptile from the Trias of Lombardy, apparently referable to *Lariosaurus*. His description was based on a small, nearly perfect specimen from Mount Perledo, showing the ventral aspect, belonging to the Senckenberg Museum in Frankfort-on-Main, which had been entrusted to him by the directors of that institution, and was exhibited before the meeting. The author pointed out the presence of a series of minute teeth on the pterygoid bones, and of an entepicondylar (ulnar) foramen in the humerus. The number of phalanges was 2, 3, 4, 4, 3 in the manus, and 2, 3, 4, 5, 4 in the pes; the terminal phalanx was flattened and obtusely pointed, not claw-shaped. In discussing the affinities of this reptile the author stated that the *Lariosaurus* described by Diecke did not appear to be generically distinguishable from the *Neusticosaurus* of Seeley, which he referred to the *Lariosauridæ*, regarding that family as intermediate between the *Mesosauridæ* and the *Nothosauridæ*, though nearer the latter. The *Mesosauridæ*, in his opinion, formed one sub-order, the *Lariosauridæ* and *Nothosauridæ* together a second sub-order, of the order *Plesiosauria*.—Dr. A. Günther, F.R.S., read a second report on specimens of reptiles, batrachians, and fishes transmitted by Mr. H. H. Johnston, C.B., from British Central Africa. Dr. Günther also read descriptions of some new reptiles and fishes, of which specimens had been obtained on Lake Tanganyika by Mr. E. Coode-Hore.—Mr. Edgar A. Smith gave an account of a collection of land and freshwater shells transmitted by Mr. H. H. Johnston, C.B., from British Central Africa. The specimens in this collection, obtained by Mr. R. Crawshay from Lake Mweru, were almost all new to science.—Mr. Edgar A. Smith also read descriptions of two new species of shells of the genus *Ennea*.—A communication was read from Dr. Arthur G. Butler, containing an account of two collections of Lepidoptera sent by Mr. H. H. Johnston, C.B., from British Central Africa.—A communication was read from Mr. Edwyn C. Reed, containing a list of the Chilian Hymenoptera of the family *Oxyneridæ*, with descriptions of some new species.—A communication from Prof. Newton, F.R.S. contained the description of a new species of

bird of the genus *Drepanis*, discovered by Mr. R. C. L. Perkins in the island of Molokai, Sandwich Islands.

Paris.

Academy of Sciences, November 13.—M. Lœwy in the chair.—On the new star of 1892, T Aurigæ = 1953 Chandler, by G. Bigourdan (see our Astronomical Column).—Observations of the comets 1893 II. (Rordame) and 1893 *c* (Brooks, 1893, October 16), made at the Paris Observatory, by the same author. Observations of position are given, extending from November 6 to 8.—Elements of Brooks's comet, by M. Schulhof. The elements of this comet closely resemble those of the comet 1864 I.—Control of the trunnions of a meridian instrument by Fizeau's interferential method, by Maurice Hamy.—Measurement of the absorption of light by thin laminæ possessing metallic reflection, by M. Salvador Block.—Determination of the true atomic weight of hydrogen, by M. G. Hinrichs. Taking as abscissæ the weights of hydrogen employed by Keiser, Dittmar, and Morley, in their respective determinations of the atomic weight of hydrogen, and as coordinates the values found, the author has obtained a diagram which indicates that the values vary according to the weight of gas used in the experiments. In his opinion this proves that the ratio of H to O is absolutely as 1 is to 16.—On baryta emetic, by M. E. Maumené. —On the production of sucrose during the fermentation of barley, by M. L. Lindet. The experiments described indicate that sucrose and invert-sugar increase proportionally to the decrease of starch during the fermentation of barley.—On the nitrification of prairie lands, by MM. J. Dumont and J. Crochetelle. The following conclusions seem to be justified by the experiments: (1) Nitrification is forwarded in soils rich in humus by the addition of small quantities of potassium carbonate (2 or 3 parts per 1000); on the other hand, large quantities of the carbonate are hurtful. (2) Potassium sulphate is efficacious, and favours the production of nitrates when about seven or eight parts per thousand are used. (3) Chloride of potassium only exercises mediocre action. (4) Sodium carbonate does not appear to favour nitrification.—On the influence of mineral poisons on lactic fermentation, by MM. A. Chassevant and C. Richet. This paper is in continuation of a previous one. The authors divide the toxic action of metallic salts on lactic fermentation into two parts, terming the dose that retards the reproduction and pullulation of the ferment *antigénétique*, while that which arrests functional activity is called *antibiotique*. It appears that the antigentic dose may be as much as three times greater than the antibiotic dose, though for certain metals the two quantities are the same.

DIARY OF SOCIETIES.

London.

THURSDAY, November 23.

Royal Society, at 4.30.—On the Photographic Arc Spectrum of Electrolytic Iron: Prof. Lockyer, F.R.S.—Magnetic Observations in Senegambia: Prof. Thorpe, F.R.S., and P. L. Gray.—Alternate Current Electrolysis: Dr. Hopkinson, F.R.S., E. Wilson, and F. Lydall.—A Certain Class of Generating Functions in the Theory of Numbers: Major MacMahon, F.R.S.—On the Whirling and Vibration of Shafts: S. Dunkerley.—On Plane Cubics: Charlotte Angas Scott.

Institution of Electrical Engineers, at 8.—The Electrical Transmission of Power from Niagara Falls: Prof. Geo. Forbes, F.R.S. (Discussion).

Sanitary Institute, at 8.—Metallic Dusts, Cutlery, Tool Making, and other Metal Trade: Dr. Sinclair White.

FRIDAY, November 24.

Physical Society, at 5.—The Magnetic Shielding of Concentric Spherical Shells: Prof. A. W. Rücker, F.R.S.—The Action of Electro-Magnetic Radiation on Films containing Metallic Powders: Prof. G. M. Minchin.

Amateur Scientific Society, at 7.—Exhibition of Lantern Slides of Recent Photographs of Volcanoes: L. W. Fulcher.——At 8.—The Dawning of Life: J. Wilson Wiley.

SATURDAY, November 25.

Royal Botanic Society, at 3.45.

SUNDAY, November 26.

Sunday Lecture Society, at 4.—Curiosities of Bird Life: Dr. R. Bowdler Sharpe.

MONDAY, November 27.

Royal Geographical Society (at the University of London, Burlington Gardens, W.), at 8.30.—Antarctic Exploration: Dr. John Murray.

TUESDAY, November 28.

Institution of Civil Engineers, at 8.—The Tansa Works for the Water-Supply of Bombay: William J. B. Clerke.—The Baroda Water-Works: Jagannath Sadasewjee.—The Water-Supply of Jeypore, Rajputana: Colonel S. S. Jacob.—On the Design of Masonry Dams: Prof. Franz Kreuter. (Discussion.)

THURSDAY, November 30.

Sanitary Institute, at 8.—Textile Manufactures, Silk, Cotton, Woollen, and Linen Industries: Dr. J. T. Arlidge.

FRIDAY, December 1.

Geologists' Association, at 8.—Notes on a Discovery of Fossils at Little Stairs Point, Sandown Bay, Isle of Wight: Thos. Leighton.—Notes on the Sharks' Teeth from British Cretaceous Formations: A. Smith Woodward.—The Breaking-up of the Ice on the St. Mary River, Nova Scotia, and its Geological Lessons: Geoffrey F. Monckton.

Institution of Civil Engineers, at 7.30.—Forms of Tensile Test-Pieces; Leonard H. Appleby.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Alembic Club Reprints, No. 4:—Foundations of the Molecular Theory: J. Dalton, &c. (Edinburgh, Clay).—Practical Agricultural Chemistry: J. B. Coleman and F. T. Addyman (Longmans).—Methods of Practical Hygiene, 2 Vols.: Prof. Lehmann, translated by W. Crookes (K. Paul).—Suicide and Insanity: Dr. S. A. K. Strahan (Sonnenschein).—Mechanics of Hoisting Machinery: Dr. J. Weisbach and Prof. G. Herrmann, translated by K. P. Dahlstrom (Macmillan).—In the High Heavens: Sir R. S. Ball (Isbister).—Collected Mathematical Papers of Arthur Cayley, vol. vi. (Cambridge University Press).—Cancer, Sarcoma, and other Morbid Growths considered in Relation to the Sporozoa: J. J. Clarke (Baillière).—International Maritime Congress, London, 1893, Sections 1 to 4. Minutes of Proceedings and General Report (Unwin Brothers).—Report of the Commissioner of Education for the Year 1889-90, vols. 1 and 2 (Washington).—Royal Natural History, vol. 1, part 1: edited by R. Lydekker (Warne).—The Beauties of Nature: Sir J. Lubbock, 5th edition (Macmillan).

Pamphlet.—Owens College Museum Hand-books—General Guide to the Contents of the Museum, 2nd edition (Manchester, Cornish).

Serials.—Bulletin Astronomique, October (Paris).—Meteorological Record, vol. xiii. No. 49 (Stanford).—Quarterly Journal of the Royal Meteorological Society, October (Stanford).—Journal of the College of Science, Imperial University, Japan, vol. 6, part 3 (Tokyo).—Journal of the Franklin Institute, November (Philadelphia).—Proceedings of the Aristotelian Society, vol 2, No. 2, Part 2 (Williams & Norgate).—Brain, Part 63 (Macmillan).—Boletin de la Sociedad Geográfica de Madrid, Tomo 35, Nos. 1, 2, 3 (Madrid).—Journal of Marine Zoology and Microscopy, No. 1 (Jersey, Sinel and Hornell).—Journal of the Polynesian Society, vol. 2, No. 3 (Wellington).

THE MUMMY.

The Mummy. By E. A. Wallis-Budge, LL.D., F.S.A. (Cambridge: University Press, 1893.)

TEN years ago, and even less, the English readers of hieroglyphs might be counted on the fingers of one hand, without the thumb. They may now be reckoned by the score. The reasons for this movement—we can hardly term it a revival—are partly the opening of the Nile to any English tourist who can afford to travel at all. This is chiefly due to the ubiquitous Mr. Cook. But it would not be fair to mention it without also mentioning such authors as Dr. Budge, who have made what used to be a sort of secret knowledge, a sort of occult science, into one of the easiest branches of learning any one, especially an Englishman, can study. Hieroglyphs appeal to several different kinds of minds. People pictorially disposed find the representations of all kinds of common objects easy to remember, and very interesting to copy. The naturalist finds these curious old birds, beasts, fishes, and reptiles well worth learning, if only to find out why they stand for letters. The astronomer must work a little at them, on account of the light they throw upon the stars of a time so remote that α *Draconis* was then the Pole Star, and not α *Ursæ Minoris*. To the ordinary lover of languages the grammar of ancient Egypt is full of delightful surprises, as well as pitfalls, while he unravels a tongue spoken by Aryans, with Semitic inflections and Hamitic roots. We might go through the whole catalogue of 'isms and 'ologies, and yet find none in which hieroglyphs would not give some help; and, above all, they are so absurdly easy. The ancient Egyptian was quite determined that whensoever people did learn to read his inscriptions, there should be no kind of mistake as to his meaning, and one result is that many beginners find it possible, without knowing the pronunciation of more than a dozen words, to ascertain the sense of whole passages. There is one thing more. At the very root of all literary learning lies this marvellous invention of the Egyptians. Hieroglyphs are the parents of the writing of the Phenicians, Hebrews, Syrians, Greeks, and Romans; and consequently they are the by no means remote ancestors of our own alphabet, every letter of which is itself a modified hieroglyph. It is therefore curious to remark that the printing and publishing of Dr. Budge's book is the first effort on the part of any university in the three kingdoms to encourage the study of Egyptology. A kind of exception may be made in favour of University College in Gower Street, which accepted a legacy left by the late Miss Edwards to found the chair now occupied by Prof. Flinders Petrie. But the work now accomplished by the Syndics of the Cambridge University Press, must be followed in the sister universities, and there are signs already of a movement in this direction. Dr. Mahaffy of Trinity College, Dublin, is known to have acquired a share in the wisdom of the Egyptians, and the university of Oxford has given the honorary degree of D.C.L. to Mr. Petrie. Under these circumstances, therefore the appearance of Dr. Budge's book is opportune. Only a few weeks ago a young gentleman was found trying to learn hieroglyphs from Sir Gardiner Wilkinson's six volumes of mingled learning and ignorance. Even in Dr. Birch's great three-volume edition of Wilkinson, there is nothing practical to be gleaned. From this time there will always be a handy work, which can be recommended to the would-be student, a work as profound in linguistic learning as it is easy and simple in communicating it. There are points in which we differ with Dr. Budge, yet we cannot exactly impute them to him as errors. For example, we do not always like his transliterations, in which he is loyal to the system now long in vogue among the best class of scholars on the continent. He has not gone in for the recent French absurdities in this respect, nor, on the other hand, has he followed Herr Erman into his impossible quests after exact pronunciation. This is not the only point on which we are inclined to quarrel with that learned and whimsical German; but it must not for a moment be supposed that there is anything controversial about the calm pages of Dr. Budge's "Mummy." On the contrary, when we consider that there is not a statement in the book that has not at one time or another been called in question, not a chapter that has not been fiercely debated, we must concede to the author a credit for moderation very remarkable. True, he has disdained even to mention the difficulties to which such books as the French catalogue of the Gizeh Museum, or M. Maspero's later works, expose a student. The method pursued by Dr. Budge is the safest. Conceivably, better systems may be constructed, but we must remember that it is by the present system that the great discoveries of Lieblein, Lepsius, Marriette, Birch, and so many others have been made.

Dr. Budge tells us in the preface that this volume was originally written to form the introduction to the *Catalogue* of the Egyptian collection in the Fitzwilliam Museum. It is, however, a complete book in itself, and forms, in a series of condensed, but perfectly clear essays, a very handy encyclopædia of all branches of Egyptology. The first five chapters are historical, and are followed by a list of the dynasties and the dates assigned to them by different authorities. The divergences here are startling. Champollion Figeac placed the first dynasty at B.C. 5867; Wilkinson at B.C. 2320. Dr. Budge evidently prefers the B.C. 4400 of Brugsch. Lists of nomes and of cartouches follow, and then we have one of the most interesting chapters in the book, that on the Rosetta stone and the recovery of the Egyptian alphabet. The priority of Young to Champollion is clearly made out, though Herr Erman is doubtful; and Mr. Renouf prefers the claims of Champollion. But Dr. Budge clearly proves that, though Young has precedence of Champollion, Akerblad, a Swede, has precedence of both. Some fifty pages are occupied by this interesting discussion, and then we come to the "piece of resistance," the title *rôle* of the whole book, namely, the Mummy. An Egyptian funeral is minutely described. Next, we are told how the mummy was prepared; a subject to which we must briefly return when we have described the rest of the contents. Mummy cloth, embroideries, canopic jars and chests, come next. Eight pages are devoted to the Book of the Dead, and then we have a careful description of the different amulets, such as inscribed

scarabs, figures, hearts, and so on, which are found in tombs. The names and figures of forty-six gods are next identified, and after them twenty-eight sacred animals. There are some interesting notes on coffins, followed by accounts of pyramids, mastabas, and tombs. A chapter contains particulars of Egyptian writing; and after some minor articles the book concludes with two lists, one of common hieroglyphic signs, and one of the determinatives most frequently observed. As the determinative is always the beginner's surest guide, this last list will probably be taken first by many readers. The scope and probable usefulness of this remarkably complete treatise will have been gathered from the above summary.

We now turn back to the middle of the volume. Dr. Budge cannot decide whether the art of mummifying was known to the aboriginal inhabitants of the lower Nile valley, or was imported from Asia by the first Aryan settlers. He speaks of the venerable stele of Shera, a dignity of the court of Sent, the fifth king of the second dynasty, whose date is placed at about B.C. 4000. This monument is preserved at Oxford, but Dr. Budge ought to have mentioned here that a portion of it is in the Gizeh Museum. The French cataloguer of that collection omits all mention of the Oxford stele. So they are even; but each portion gives different items of information. On this monument Shera prays the gods "to grant sepulchral meals," from which Dr. Budge infers "that the art of elaborate sepulture had reached a high pitch of perfection in those early times." He notes incidentally that a redaction was made in the reign of this king Sent of a medical papyrus, from which it is clear that the Egyptians were already possessed of anatomical knowledge sufficient to enable them to preserve the human body as a mummy or otherwise. Manetho, the Ptolemaic chronicler, expressly states that Teta, the second king of Egypt, wrote a book on anatomy, and also studied the properties of drugs. His mother, Shesh, invented a hair-wash. Although, then, some form of mummifying must have been in use at a very early period, it does not follow that it was always practised. Bodies were sometimes preserved in honey, as, for example, that of Alexander the Great; and Dr. Budge quotes a gruesome story from Abel el Latif, about the body of a child found in a jar of honey. The body of Mycerinus, now in the British Museum, seems to have been wrapped in cere-cloth—if the Egyptians had honey, they also had wax. Skeletons of this ancient period usually fall to pieces when exposed to the air. The oldest mummy, strictly so called, which has been identified, is that of Seker-em-sa-f, B.C. 3200, a king of the sixth dynasty, which is now at Gizeh. A few fragments of the mummy of Unas, of the fifth dynasty, are in the same collection—part of the skull, only, and a hand. As to mummy cloth, Dr. Budge corrects a prevalent error. Almost all the older writers asserted that mummies were wrapped in cotton. Jomard thought linen was also used; but a learned Fellow of the Royal Society, having obtained, in 1834, four hundred specimens of bandages, ascertained that they were all of linen. A piece of fine texture was found to have five hundred and forty threads to the inch in the warp, and one hundred and ten in the woof. Nobody who has seen the wrappings, of a delicate salmon colour, which were in the coffin of Thothmes III., can forget that they were as fine as the finest lady's handkerchief of the present day. Dr. Budge's views on the subject of pyramids will not tally with those of numerous very worthy persons now, we may hope, of a more reasonable mind. In Cairo, a very short time ago, the only book on pyramids to be had by tourists was that of the late Scottish Astronomer Royal, which was written to prove that the Great Pyramid was erected to embody the truths of revealed religion. Dr. Petrie's book was nowhere to be seen. Now all is changed. Messrs. Cook and Son employed Dr. Budge to write a little book on the Nile voyage, a copy of which is in the hands of every tourist, and the pyramid inch and the great passage theory have become curiosities of history. Dr. Budge says briefly, "the royal tombs of the early dynasties were built in the form of pyramids, and they are, to all intents and purposes, merely mastabas."

ESKIMO LIFE.

Eskimo Life. By Fridtjof Nansen. Translated by W. Archer. 350 pp. (London: Longmans, Green and Co., 1893.)

WHEN Dr. Nansen reached the west coast of Greenland, after his memorable journey across the continent, he found that the last ship of the year had left for Europe, although he had altered his plans and steered for Godthaab instead of the more northerly Christianshaab, partly in order to avoid being detained in the country during the winter. He was, however, compelled to spend the winter among the Eskimos, and his observations and reflections on the character and every-day life of the race are embodied in the book before us.

Dr. Nansen admits the impossibility of attaining a complete and thorough knowledge of so peculiar a people in so short a time as one winter, but his own experiences and impressions have been supplemented by reference to the writings of all the most competent authorities—the Egedes, Crantz, Rink, Holm, and others.

The early history of the Greenland Eskimo is obscure, and anything like certainty dates back no further than 1721, when Hans Egede, the Norwegian missionary, took his wife and children, and settled on the west coast with a view of improving and civilising the native race. From that time to the present, however, the history of the people is well known, and a study of this period affords one of the best examples of the development and changes which so-called lower races undergo, when subjected to the influence of western European civilisation.

The first part of Dr. Nansen's book is concerned with the daily life of the modern civilised Greenlander, and the chapters on the kaiak, or skin-boat, and the weapons used in hunting the seal and other characteristic game of the Arctic seas are excellent.

It is interesting to note that this section of the Eskimo race use the throwing-stick, which enables them to throw the harpoon and bird-dart with greater force and accuracy than with the unaided arm alone. This instrument is only met with among two or three races of men, so widely separated from each other as to preclude the idea of a common origin of the invention.

The character and social life of the people is portrayed in three or four of the succeeding chapters. [Little

acquaintance with the writings of Nansen is necessary before it is seen that he possesses a flexibility of mind and deep sympathies which enable him to enter into peculiar touch with a race of this character.

Chapter xiii. deals with the religious ideas and myths of the Eskimo. This part of the volume is necessarily second-hand; but so far as the facts are concerned, nothing remains to be desired. It seems to us, however, that there is too great a tendency to look upon these legends and tales as matters derived from foreign influence, notably that of the early Scandinavian explorers, from the time of Erik the Red (986 A.D.) to about 1400 A.D. There is some similarity between the legends of the Scandinavian and the Eskimo, but Dr. Nansen, in dealing with the origin of those possessed by the latter, does not apparently allow enough for the possibility of spontaneous growth of the same idea in two widely separated races. The Vikings have had little influence upon the daily life of the Greenlander, and it is very improbable that the latter would borrow recondite philosophy, or lore of any kind, from the former.

If true similarity does exist in such cases, it is more likely to be due to the inherent similarity of the powers of the human mind to invent explanations for incorrectly understood phenomena.

In the concluding chapters are given the results which have been achieved since the introduction of Christianity 150 years ago. The first European settlement found a people who were nearly blameless, full of practical socialistic sentiment, generous and open-hearted, truthful, private property almost unknown, poverty non-existent, able to live peacefully and contentedly in surroundings in which Europeans, with all modern resources, are taxed to the utmost to exist through winter, healthy and full of patience. To-day disease, poverty, and distress are abundant. These changes, which must be looked upon as bad for the Eskimo, whatever the intentions of the settlers may be, are brought about by causes which are to a large extent obvious, and Dr. Nansen's advice to all those who have the welfare of the native race at heart, is to leave the country, and allow the people to make the shortest cut back again to their pristine state.

The translator's work has been admirably done.

J. P.

OUR BOOK SHELF.

La Voie Lactée dans l'Hémisphère Boréal. By C. Easton. With a preface by Prof. H. G. van de Sande Bakhuyzen. (Paris: Gauthier Villars et Fils, 1893.)

THE Milky Way, "that broad and ample road, whose dust is gold and pavement stars," almost defies accurate delineation. Its irregular outlines and indefinite structure tease the eye of the artist, and renders his task most difficult. In all probability the largest amount of information with regard to this celestial zone "powdered with stars" will be obtained from photographs taken by means of portrait lenses having a wide field, similar to that employed by Prof. Barnard for his beautiful pictures. There is much to be gained, however, by the multiplication of maps such as those of M. Easton, in which the aspect of the Galaxy to an observer having normal eyesight is shown. The maps are finely drawn and reproduced, and well show the delicate gradations of galactic light. A detailed description and historical notice give the atlas additional interest, while a catalogue of the patches and streams of luminosity, and the dark regions, will be of use to those who theorise on the structure of the stellar universe. A comparison of the maps with those drawn by Boeddicker reveals many differences, but it cannot be said on this account that either of the observers is wrong. No two observers have eyes exactly alike, or are favoured with precisely the same observing conditions, hence drawings of the Milky Way, like those of nebulæ, simply represent the appearances presented to certain visions, and are only approximations to the truth. M. Easton's maps are published in a very handy form, and may be added with advantage to every astronomical library and observatory.

An Elementary Treatise on Analytical Geometry. By W. J. Johnston, M.A. (Oxford: Clarendon Press, 1893.)

IN these 400 pages Mr. Johnston has ably succeeded in producing a very excellent treatise which leads the beginner by easy stages from the first principles of the subject to the more complicated theorems in trilinear coordinates. In the first ten chapters the student is made thoroughly familiar with the properties of the Ellipse, the Parabola, and the Hyperbola, after having been well exercised in the more preliminary parts of the subject as regards co-ordinates, the straight line, loci, &c. In these chapters it seems that the beginner can hardly fail to obtain a thorough grip of their contents, unless indeed he goes out of his way to do so, for more details could hardly be added. The numerous worked-out exercises should also be valuable, as they show him how to apply the knowledge gained from the various theorems learnt as book work. The next three chapters deal with the general equation of the second degree, confocal conics, and abridged notation, the last-mentioned including a large number of miscellaneous exercises; in these may be mentioned some additional methods of tracing a conic whose Cartesian coordinates are given, and an investigation of the equation of a diameter due to Prof. Purser. The remaining chapters treat of trilinear coordinates, envelopes, and methods of transformation. Here may be noticed Prof. Genese's proof of Feuerbach's theorem, Pascal's theorem, and many others of interest.

As an elementary book one may say that, from a beginner's point of view, we have here a sound and clearly written volume that will be sure to find favour with students and teachers. Perhaps it may be better for those commencing the subject to pursue the limited course recommended to them by the author, but a little more of an insight will show them what to read. Advanced students will also find much of interest in the latter chapters, and to them we can specially recommend the working out of some of the numerous and well-chosen examples.

Zur Kenntniss der Postembryonalen Schädelmetamorphosen bei Wiederkauern. By H. G. Stehlin. (Basel; Benno Schwabe, 1893).

THIS publication deals with a branch of osteology which up to the present time possesses no special literature of its own, and is an attempt to trace the changes which take place in the skulls of ruminants from the time of birth up to adult age. The skulls of Bos, Capra, and Portax are studied in a most exhaustive manner at different ages, and comparisons drawn; elaborate measurements being given in every case. Special attention is paid to the effects produced by the development, final size, and position of the sinuses, teeth, and horns; also, the differences between the skull at birth and at adult age are considered in relation to rate of growth of the animal, and its length of life. In the last chapter the three types, Bos, Capra, and Portax, are contrasted with each other, and a number of other forms described, their relations to these types being indicated.

The plates illustrate most fully the points made out, in many cases a longitudinal section of the skull of the animal at birth being printed in red over a drawing of one of adult age, both drawings having been reduced to scales which render comparisons of form possible.

Suggested Nomenclature of Radiant Energy.

Having recently had occasion to develop the first principles of the theory of inter-stellar radiation, I soon felt the want of some short and convenient word to express that form of ethereal wave-effect known as "radiant energy," "radiant heat," "light," "rays of the spectrum," &c. Radiant energy is doubtless the most accurate of these expressions, but it is subject to the objection of being a description rather than a name. The nomenclature of the subject has come down from a time when it was supposed that there were three distinct kinds of rays in the spectrum, severally known as light, heat, and actinic rays. It is, I believe, not much more than half a century since several eminent physicists and teachers supposed that the heat rays of the spectrum could be separated from the light rays having equal refrangibility by the absorption of a transparent medium; and that even the light rays of different colours might be separated in the same way. I cannot but think that the general understanding and application of the now received theory of the subject, which recognises in this form of energy no differences of kind except wave-length, has been materially retarded by the want of a corresponding nomenclature.

The use of the word "light" for ethereal waves having a length between certain definite limits, while there is no corresponding word for other waves, is evidently unscientific. Notwithstanding the great practical usefulness of light, its distinctive property of affecting the optic nerve in a certain way can claim only a secondary place in physics. Indeed, it has long seemed to me that the banishment of the word "light" from physics was a desideratum.

After various attempts I hit upon the very simple term *radiance*, as one which seemed well-fitted to supply the want in question. The vague and poetic idea hitherto associated with it is an advantage, because it enables us to adapt it to the case in hand with greater readiness than we could adapt a word which already had some well-defined meaning. Shakespeare speaks of the "sacred radiance of the sun"; while Milton describes the Deity as "Girt with omnipotence, with radiance crowned." We can thus adopt the word to express scientifically what we now consider to be electro-magnetic waves, or ethereal waves, without that clashing of ideas which might arise from making a new application of an old word, and without the awkwardness of coining a new one.

The necessary derivatives and compounds of the word can be formed with as much ease as we should expect in the case. The verb "radiate" will mean to emit radiance. I do not think any confusion will arise if we use the word "illuminate" to signify the throwing of radiance upon a material body, although in ordinary language it implies light. Possibly the extent to which it is used in a tropical sense may facilitate the widening of its literal meaning. *Radiometry* would mean the measure of radiance, and an instrument for effecting such a measure would naturally be called a radiometer. It is perhaps unfortunate that the instrument in question should then assume the name of Crookes' beautiful little instrument, but an apology may be found in the fact that the latter has not been used for the purpose of exact measurement. The use of the word "radiometry" offers no such difficulty.

I am still a little perplexed for a word which shall express the quality hitherto called transparency, diathermancy, &c. Apparently we have no alternative but to continue the use of one of these objectionable words, or invent some such new word as transradiant, or transradious.

The proper measure of radiance, and the only measure which can be regarded as of real importance in physics, should be the amount of energy radiated in unit time. This measure is equivalent to that of heat generated in unit time in the absorption of radiance by a perfectly black body. If we reflect that this, and this alone, measures the actual loss of internal energy by a radiating body of any kind, whether ball of iron in a laboratory, planet, star, or nebula, the importance of some simple nomenclature of measurement will be evident. I should be much pleased if physicists would find by actual trial whether the use of the proposed words comes as natural to them as it has to me.

Simon Newcomb.

The Postal Transmission of Natural History Specimens.

It has always been recognised that scientific research is greatly furthered by the exchange of the various objects with which that research is concerned. For the transmission of objects of Natural History from one country to another, the mails have offered a cheap, speedy, and trustworthy means. Heretofore, through the laxity with which the regulations on the subject have been enforced, it has been possible to enter such objects in the mails of the Universal Postal Union as samples of merchandise and under the rates of postage therefor. From official information lately received from the Post Office Department of the United States it appears that such a rating is entirely unauthorised by existing provisions, and that objects of Natural History may be mailed to countries of the Union only, at the rates required for letters. The United States Post Office Department also stated that it had recently submitted a proposition to the countries composing the Postal Union to modify the regulations so that such specimens might be received into the mails at the same rates as samples of merchandise, but that a sufficient number of those countries had voted against the proposition to defeat it.

This Academy has therefore resolved to address the various scientific bodies, with which it is in communication, in those countries whose Governments have voted against the proposition, and to request those scientific bodies to memorialise their respective Governments in favour of the same.

The Governments of Austria, Bolivia, British India, Canada, Germany, Great Britain, Guatemala, Hungary, Japan, Norway, Portugal, Russia, Spain, Sweden, Tunis, Uruguay, and Venezuela having voted in the negative, this Academy respectfully requests the favourable consideration of this question by scientific societies, and begs that they take such steps as they deem advisable to inform the Postal authorities of their respective Governments of the manifest advantages to scientific research which would result from the adoption of the proposed modification, and to request those authorities to take such steps as may result in the adoption of the same.

The letter rate for postage (Universal Postal Union) is ten times that required for samples of merchandise; such a rate for specimens of Natural History is virtually prohibitive.

This Academy would respectfully urge upon scientific societies prompt action in this matter, if it meets with that approval which we so strongly desire.

Flame.

However thoroughly a B.A. audience may have allowed Prof. Smithells, by means of his beautiful experimental demonstrations, to hypnotise them into unquestioning belief in his conclusions, those who read the account of his lecture in the pages of Nature will not all be equally disinclined to question the validity of some of his arguments.

To tell us that Dalton, as a matter of fact, long ago *settled* the question as to which has the preference—the carbon or the hydrogen—when a hydrocarbon is burnt with insufficient oxygen, is, after all, but to appeal to the gallery; and this and other conclusions arrived at by Prof. Smithells appear to me to involve the use of that process of circular reasoning which consists in taking for granted that which is to be proved—a method which at the present day finds such favour in certain quarters.

As I discussed this matter somewhat in detail in a correspondence with Sir G. G. Stokes last year (Chem. Soc. Proceedings, 1892, No. 106, p. 22), it is unnecessary to go fully into it now. Any number of analyses showing the presence of hydrogen in the products of combustion may be quoted without materially ad-

vancing the settlement of the question. In my opinion, there is no improbability inherent in the assumption that hydrogen is but a secondary product, resulting from the interaction of the primary products—water and either carbon or carbon monoxide. The rate at which the interactions take place in flames are such, and the conditions are such, that the products *collected* are probably far from being the *products of the initial interchanges*, as indeed Prof. Smithells himself admits to be the case. It is scarcely likely that the settlement of such a question can ever be achieved by direct observation. Our ultimate views on the nature of the changes occurring in flames must depend on the gradual growth of a true understanding of the nature of chemical interchanges in general, and especially in gases.

I am inclined to take the same view with reference to Davy's explanation of the luminosity of flame. If eventually, as is not improbable, we come to regard the expressions *chemical interchange* and *electrolysis* as interchangeable equivalent terms, much more will have to be said on behalf of Frankland's hypothesis. I had the good fortune to attend the philosophic lectures at the Royal Institution in which Frankland, in 1868, first fully stated his views on this subject, illustrating his arguments by a series of most striking experiments. No course of lectures ever impressed me more, and to the present day I have the most vivid recollection of all that passed. An account af the lectures was published in the *Journal of Gas Lighting* at the time of their delivery. It has always appeared to me that Frankland's arguments are of a most weighty character, and that owing to their appearance in an obscure publication they have never yet been sufficiently widely considered.

The study of flame affords problems of the highest interest and importance, but of proportionate complexity and difficulty. There is little doubt, however, that we are inclined to take too narrow a view of this as of many other inquiries—that we have an unreasoning belief in what we are pleased to call facts, forgetting that these same "facts" are but phenomena interpreted by our own limited intelligence. On studying the views that have been taken at various times, it is only too obvious that fashion is not confined only to garments, nor is dogma the exclusive privilege of theologians; and it is time that we realised that very many of our conclusions regarding chemical interchanges are but the crudest dogmas, based on a thoroughly superficial consideration of the phenomena. If we are to deserve the title of scientific workers—workers exact in deed, thought, and word—we must be far more careful in the choice of our language, and guarded in our conclusions.

HENRY E. ARMSTRONG.

"Geology in Nubibus."

SIR HENRY HOWORTH wishes to continue the discussion of glaciation in the pages of NATURE, but I find in his last letter very good reason why this cannot be done. No discussion can lead to definite results unless the parties to it accept as data what they themselves have recently and deliberately admitted. But when I stated that the Rhone glacier *did* reach the Jura, and deposit on it erratic blocks between Geneva and Soleure, I did so because it was one of the data already admitted by Sir H. Howorth. In his "Glacial Nightmare," pp. 169-173, he gives a full summary of Charpentier's first memoir on the erratic blocks of Switzerland, describing the glacial phenomena exhibited along the whole course of the old glaciers from the Alps to the Jura, and showing that they "even climbed that range and went over to the other side of it." Sir H. Howorth then says: "I have quoted at considerable length from this excellent memoir, because I look upon it as having definitely applied *inductive methods to this question* with results which are for the most part *sound and unanswerable*." (Italics mine.) In the same chapter (pp. 195-202) Charpentier's second memoir is summarised still more fully, and his general conclusion is thus quoted: "It goes without saying that not only all the valleys of the Valais were filled with ice up to a certain height, but that all lower Switzerland, in which we find the erratic débris of the Rhone valley, must have been covered by the same glacier. Consequently all the country between the Alps and the Jura, and between the environs of Geneva and those of Soleure has been the bed of a glacier." Agassiz and other writers are quoted as giving further evidence of the same kind. Nowhere in the whole of this chapter can I find a single objection to the conclusions of the chief writers quoted, and the concluding paragraph, at p. 208, frankly accepts them. It declares that they are supported by "every form of converging evidence," and that—"So far there is no question at issue." Yet, when I take these same conclusions of Charpentier as admitted data, Sir H Howorth says: "This form of dogmatic argument is assuredly incomprehensible!" Charpentier's proof that the Rhone glacier reached Soleure, was, a year ago, "sound and unanswerable," and was an example of "definitely applied inductive methods"; but when I accept these same results as something to reason upon, I am told that I am making use of "hypotheses outside the laws of nature." I have now justified my opening statement that a discussion carried on in this manner can serve no useful purpose. ALFRED R. WALLACE.

Correlation of Magnetic and Solar Phenomena.

IN Mr. Ellis' letter on this subject (NATURE vol. xlix. pp. 30), he says:—

"To sum up, the points of the matter may be thus stated:—(1) The solar outburst in 1859 was seen independently by two observers: the fact of its occurrence seems therefore undoubted. (2) The corresponding magnetic movement was small. (3) Many greater magnetic movements have since occurred. (4) No corresponding solar manifestation has been again seen, although the sun has since been so closely watched."

Now, in the year 1882, I was acting as assistant to the Solar Physics Committee, and on November 17 there was a dense fog, so that it was not possible to take the usual solar observations. Mr. Lockyer was present in the morning, and then left for some reason; after he had gone, a telegram came for him; he returned late in the afternoon, and sent for me, told me the telegram was from Mr. Preece, of the Post Office, asking him whether there was a solar disturbance, as there was such a violent electrical storm raging, that communication had been cut off from the continent, and that it was difficult to maintain communication in England. I at once went to the instruments, and as the fog cleared just before sundown, was able to ascertain that there was a large group of spots near the sun's meridian, attended with most violent uprushes of luminous matter; indeed, if my memory serves me aright, it was the most violent disturbance I saw during the whole of my observations, extending from 1879 to 1886. On reporting to Mr. Lockyer, he said we should probably see an aurora in the evening; and as soon as it was dark, there was a most brilliant auroral display that exhibited some quite new features (NATURE, vol. xxvii. pp. 82 *et seq.*) Doubtless, had this spot been kept under observation, luminous outbursts similar to those observed by Carrington and Hodgson would have been seen; indeed, Mr. Whipple's letter (*loc. cit.* p. 83) seems to contain such an observation.

I believe, but am not quite sure, as the records of the observations are in Mr. Lockyer's possession, that it was in this spot that he and I first noticed that some of the so-called iron lines in the spot spectrum were in motion, while others were not. H. A. LAWRANCE.

Gunnersbury, November 19.

New Variable Star in Andromeda.

A STAR that should be added to the list of variables is $+26°43$, of the Bonn *Durchmusterung*, in which work its magnitude is given as 8·7. In reply to a letter of mine, in which I expressed a doubt as to this star's existence, Dr. Küstner, of Bonn, informed me that although he had on the 7th of this month looked in vain for the star with the 6-inch refractor of Bonn Observatory, yet it seemed pretty certain that a star had twice been observed in the specified place in September, 1855. I have subsequently been informed by Sir Robert Ball, that the star was twice observed at Cambridge (England) in 1878. The dates and places of the various observations, as well as the estimated magnitudes, are:—

Sept. 7, 1855, Bonn, 9·0 (but perhaps 9·2).
Sept. 10, 1855, Bonn, 8·3.
Nov. 29, 1878, Cambridge, 8·7.
Dec. 11, 1878, Cambridge, 8·7.

The star's mean place for 1894·0 is

R.A.	0h.	16m.	51·3s.
Decl.	+26°	24′	27″

THOMAS D. ANDERSON.

Protective Habit in a Spider.

Mr. R. I. Pocock's interesting paper in your issue of November 16, leads me to place on record an observation I made last summer in the island of Arran. Sitting by a little clear pool in the granite of Glen Sannox, I noticed a spider whose web was spun in the heather which partly overhung the stream. On disturbing her, she dropped on to the granite a few inches above the water, and running rapidly down, entered the pool and hid under a tuft of weed. After remaining thus hidden for $2\frac{1}{2}$ minutes, she returned to the surface and, reeling herself up by her thread, regained the web. Disturbed again, she repeated the action, remaining under water $1\frac{3}{4}$ minutes. A puff of tobacco smoke sent her down a third time, when she remained hidden for $2\frac{1}{4}$ minutes. In each case she hid in the same place, and in each case regained the nest by her thread.

I have placed the spider in Mr. Pocock's hands. He informs me that the species is *Epeira cornuta*, or possibly *patagiata*.

University College, Bristol. C. Lloyd Morgan.

THE LOSS OF H.M.S. "VICTORIA."

FOUR weeks ago the Admiralty issued a minute upon the proceedings of the Court-Martial appointed to inquire into the loss of H.M.S. *Victoria*; and also a further minute upon the construction and stability of the ship, and a report by Mr. W. H. White, the Director of Naval Construction, upon such parts of the evidence given at the Court-Martial as throw light upon the causes of the foundering or capsizing of the ship.

In the first-named minute the Admiralty concur with the finding of the Court-Martial, as regards the causes of the collision with the *Camperdown*, and the distribution of blame among the officers concerned :—matters with which we shall not now attempt to deal. The other two relate to the construction, buoyancy, and stability of the ship, and discuss facts and questions relating to these points, which demand the careful attention of all who are interested in the efficiency of the Navy. These minutes deal with matters for which the Admiralty is felt to be responsible, and to be, to some extent, upon its trial. The question of Admiralty responsibility for the efficiency of the *Victoria*, and her power to withstand such a blow as she received, has been hitherto treated and discussed as though it were merely one of who designed the ship. In this case, the circumstances are somewhat peculiar, for her original designer, Sir N. Barnaby, retired from the Admiralty service in 1885, immediately after the vessel was ordered to be built, and before she was even in frame. Many alterations were afterwards made during the progress of construction, and everything considered necessary for safety or efficiency was done by others, during the five years that passed before she was finally completed. Whether the early design were good or bad, the responsibility for the ship as she was completed and commisssioned, and passed into the Navy as a first-class battle-ship in 1890, surely rests with those whose duty it was to watch her construction, and to ultimately certify to her fitness for the class in H.M. service in which she was placed. The question of who was responsible for the design of the *Victoria* as it first stood, has now little more than an historical interest. That of the responsibility for completing and fitting her out for sea, and passing her into the Navy as a first-class battle-ship, is the only one of real practical importance at the present time, if it be thought necessary to discuss the matter.

This being the state of the case with regard to the question of responsibility, we can only regard the minutes relating to the buoyancy and stability of the *Victoria* as the best defence of the ship that is possible. It may be a perfectly good defence, but it is obviously *ex parte*, and can only rightly be judged as such. Had a Committee of Inquiry been appointed, these minutes represent the case that would have been laid before it by the Admiralty, and would have been examined from various points of view, and adjudicated upon. The Admiralty has preferred to treat the public as competent judges, and to lay their case before them in a form which bears the outward semblance of a judicial decision. The minutes are, however, upon some points more in the nature of a pleading than a judgment; while they are, at the same time, much too technical and complex for any but the most competent experts to judge. It is to be regretted, in the interests of the Navy and the country, that the facts and opinions thus put forward are not referred to a competent and impartial body for examination and report.

Mr. White's report summarises the evidence respecting the behaviour and movements of the *Victoria* after she was struck by the *Camperdown*, and gives the results of calculations respecting the effect of filling compartments in the neighbourhood of the blow, which appear to agree, in the main, with the reports of observers. The calculations employed are, as he states, quite simple in character; and no one who knows the Construction Department of the Admiralty, or the men in it who perform this class of work, could doubt their substantial accuracy. An important point in connection with them is, however, the assumptions upon which they are based. Some of these may be more or less open to question; while nothing is said as to the information the officers had respecting the rapidity with which the *Victoria* might be sunk if rammed. It appears evident that no one on board imagined the ship could sink, after such a blow as she received, without giving time to close the water-tight doors; and it appears, also, that some of the water-tight doors could only be closed by going into compartments into which the sea first obtained access.

These questions, and the more general one of the light that is thrown upon the efficiency of other ships of the same class by this sad disaster, respecting which the Admiralty minutes say nothing directly, though they imply that nothing unsatisfactory is indicated, appear deserving of close and careful consideration. The following remarks will be devoted to an attempt to describe how the matter, and the light thrown upon it by the recent Admiralty minutes, strikes one who is intimately acquainted with the ships of the Navy, and has studied the technical questions which have been raised, from time to time, respecting them.

The subjects treated of in the two minutes now under consideration may be classified as follows:—(1) The nature of the blow received by the *Victoria*; (2) her after-movements and behaviour up to the moment when she capsized and sank; (3) the extent to which water found access into the ship; (4) the effect of the water thus admitted upon the line of flotation and the stability; and (5) the lessons that are taught by various circumstances attending the loss that have come to light.

1. *The nature of the blow received by the "Victoria."*—Before the commencement of the manœuvre that immediately preceded the disaster, the ships of the squadron were steaming in two parallel lines, about 1200 yards apart, at a speed of about $8\frac{3}{4}$ knots. The course was ordered to be reversed by turning the ships inwards between the lines. The *Victoria's* helm was put hard to starboard, at an angle of 35°, and the *Camperdown's* helm was put over to port, at an angle of 28°. With these helm angles the *Victoria* would turn in a circle of 600 yards diameter, and the *Camperdown* in a circle of 800 yards diameter. A collision was therefore inevitable with both ships continuing at the same speed. When both had turned through eight points, or a right-angle, they were end-on to each other, at a distance apart which was estimated at 400 to 500 yards. It was then seen that a collision was imminent, and the port engines of the *Victoria* and starboard engines of the *Camperdown*

were ordered to be reversed at almost the same instant, about one minute before the collision, in order to make the ships turn more quickly. Orders to go astern with both sets of engines followed immediately in each ship.

The *Camperdown's* speed on striking the *Victoria* was estimated at 5 to 6 knots, and appears to have been rather less than 6 knots. The *Victoria's* speed ahead at the same time was about 5 knots. The blow was struck at an angle of about 10° abaft the beam of the *Victoria*, and at a distance of about 65 feet abaft the stemhead. The vertical portion of the *Camperdown's* stem penetrated 5½ to 6 feet into the side of the *Victoria*, and the point of the ram, which projects 7 feet beyond the vertical portion of the stem, penetrated 9 feet within the bottom plating at a depth of about 12 feet below water. The breach thus made in the side of the *Victoria* appears to have been 220 or 230 square feet in area; of which over 100 square feet was below the water-line. It extended vertically downwards 28 feet from the upper deck, and 18 feet from the water-line, and was 12 feet wide at the upper deck, and 11 feet wide at the water-line. The ships were locked together for over one minute, during which time their sterns swung together through an angle of 20°. As the blow was struck just before a water-tight transverse bulkhead, it appears probable that the water-tightness of the division thus formed was destroyed, either by the first shock or by injuries subsequently received, as the sterns of the two ships swung towards each other, while they were locked together.

2. *The movements and behaviour of the "Victoria" after being struck, up to the moment when she capsized and sank.*—Mr. White gives a clear description of this, which agrees with the evidence of officers on board other ships, who observed carefully what was happening to the *Victoria*. The force of the blow given to the bow of the *Victoria* caused it to move over at first 60 or 70 feet to port. The two ships remained locked together about one minute,[1] and as the *Camperdown* moved astern and cleared the *Victoria* settled down rapidly by the bow, and heeled towards the starboard side. The bow sank 10 feet during the first four minutes after the collision. Two minutes later the water had risen so high on the forecastle, which was originally 10 feet above water, that the men working there had to be called away. In nine to ten minutes after the collision the sea was entering the open turret ports, 100 feet from the bow and 14 feet above the original waterline. The upper deck right forward was then 13 feet below water; the armour-door in the bulkhead at the fore end of the upper deck battery, which was open, was partly under water; and the two foremost gun ports on starboard side, also open, were awash. The forward part of the upper deck was thus submerged for nearly half the length of the ship, and the stern was lifted about 8 feet. Simultaneously with this rapid depression of the bow and elevation of the stern, the ship was continuously increasing her heel to starboard up to about 20°, and when this position had been reached, nine or ten minutes only after the collision, she gave a lurch to starboard, turned bottom up, and sank by the head. When the lurch began the vessel was steaming slowly ahead with both screws, and the helm was hard over to starboard.

The speed ahead, due to an attempt to steam slowly towards the land, and the helm being over to starboard, tended somewhat, as Mr. White points out, to increase both the depression of the bow and the heel to starboard. Even a very low speed would have a serious effect, after the fore end of the upper deck became submerged, in forcing it still deeper below water, and in driving water into the interior of the ship through the openings on and above the upper deck. The helm was kept over because the hydraulic steering gear ceased to act very soon after the collision, when it was in that position. The failure of this steering gear is attributed to the inflow of water consequent upon the collision. Alternative hand-steering gear, which was available in a convenient position abaft the portion of the ship that was flooded, could not be brought into operation, owing to the short time the ship remained afloat.

[1] Some observers thought two minutes.

3. *The extent to which water found access into the ship.*—A very large portion of Mr. White's report is devoted to a detailed discussion of the state of each compartment in the forward part of the ship, and the probability of water finding access into it; and, although the results thus arrived at are, doubtless, right upon the whole, it is not certain that they are correct in every particular. He appears to go too far in asserting that the evidence given before the Court Martial, respecting the compartments which were flooded, is exhaustive; while this is inconsistent with the list, given in Table II. of his report, of "Compartments shown by the evidence to have been probably or possibly filled through doors, hatches, &c." Two items in that list, at least, are quite doubtful, as judged by the published evidence, viz. the water-tight compartment in hold on port side, between frame stations 12 and 22, and the port ejector tank; which would hold 108 and 35 tons of water respectively. Neither does it appear right to claim, with absolute certainty, upon the evidence as it stands, that the submerged torpedo room was flooded, although it is probable that it was. This is a point upon which further examination of the witnesses might have converted reasonable doubt into something approaching to certainty.

There are, however, no scientific or practical questions relating to the case that would be seriously affected by proving absolutely that one compartment, or another, about which there might be any doubt, was or was not flooded. Events proved that sufficient water found its way into the fore-end of the ship to submerge the bow to the extent that was observed, and to ultimately cause her to capsize and sink. She would probably have kept afloat if all water-tight doors and scuttles had been closed, and if the entry of water had thus been limited to the compartments that were directly opened up by the breach made by the collision. The ultimate submersion and capsizing was apparently caused by the entry of water into compartments that were not damaged by the collision, through open doors and scuttles; and the circumstances and causes of the catastrophe can therefore be thoroughly discussed whether Mr. White be right or wrong in his conclusions as to the precise number and positions of the compartments that were flooded.

It thus appears, adopting Mr. White's figures in the aggregate—which must be fairly correct in order to account for the facts—that the weight of water which entered the ship was approximately as follows:—

(1) Into compartments that would have been flooded, in consequence of the collision, if all water-tight doors and hatches had been closed: 75 tons above the protective deck, 330 tons upon the platforms under the protective deck, and 271½ tons in the hold, being 676½ tons in all. (2) Into compartments that were subsequently flooded through doors, hatches, &c., that were left open: 33½ tons above the protective deck, 353 tons upon the platforms under the protective deck, and 47 tons in No. 7 coal bunker and shoot. (3) Into compartments which may have been flooded, but as to which the evidence is doubtful: 322 tons above protective deck,[1] 200 tons upon the platforms under the protective deck, and 143 tons in the hold. In addition to the above about 100 tons of water must have entered the boatswain's and carpenter's stores above the protec-

[1] The compartments into which this 322 tons of water may have entered are the air-compressing room, sail room, chest room, torpedo room, and turret support, and it is pointed out in a foot-note to Mr. White's minute that these compartments are within the limits of the armour belt. We do not understand how this affects any of the points in the case.

tive deck, through the riding bitts on the upper deck, after the tops of these became submerged.

We thus obtain a total of 1,110 tons of water which entered the ship through the breach made by the collision and passed into other compartments, besides those directly laid open to the sea, through open doors, hatches, &c., a further amount of 100 tons that entered after the tops of the riding bitts became submerged; and 665 tons about which there may be doubt as to the precise positions of the compartments it entered.

4. *The effect of the water thus admitted upon the line of flotation and the stability.*—The 1,110 tons of water above mentioned would, according to the Admiralty calculations, considering its position at the fore-end of the vessel, depress the bow to the extent of 21 feet, and raise the stern 8 feet. This change of waterline is considered to have necessarily flooded the other compartments, respecting which the direct evidence is doubtful; and certainly to have filled the boatswain's and carpenter's stores through the riding bitts. The turret ports, and also the door on starboard side, and the ports, in the upper deck battery, would thus be brought under water, and the position of the ship be rendered hopeless.

Mr. White states, with regard to the stability, that as the *Victoria* floated before the collision, she had a metacentric height of 5 feet—*i.e.* the centre of gravity was 5 feet below the point at which its righting effect would be *nil*—and that after the collision, when the bow had sunk deeply and she had heeled considerably—by how much is not said—the metacentric height was reduced to about eight-tenths of a foot. When water had entered the battery and turret through the open door and ports, as observed when the fatal lurch began, the metacentric height had become altered by the changed condition to *minus* 1·8 feet; and the final capsize was inevitable.

A consideration of the fifth subject treated in these minutes, which is the lessons taught by circumstances connected with the loss—the most important of all for the future—will require an article to itself, and must therefore be postponed till another week. The points mentioned in this connection are: the effect of longitudinal bulkheads upon safety in such circumstances as are those under discussion; whether the closing of the battery doors and ports would alone have been sufficient to save the ship; whether the closing of all water-tight doors and scuttles would have done so; whether the water-tight doors fitted to the ship were the best for the purpose; the value of an armour-belt at the ends for the purpose of resisting damage; and whether the blame rests wholly upon the officers of the *Victoria* for not knowing how rapidly the ship would be likely to sink when damaged as she was, and for not taking steps sooner to close the water-tight doors and scuttles and prevent the final catastrophe.

Francis Elgar.

JUPITER AND HIS RED SPOT.

JUPITER is now, with his northern declination of 18° and an equatorial diameter of 48″, a very fine object visible above our horizon during more than 15 hours at a time. Thus, on December 1 he rises at 3h. 7m. and sets at 18h. 23m., shining nearly throughout the long nights now prevailing from a position about 6° south-south-west of the Pleiades.

As an object for telescopic study Jupiter is undoubtedly the most interesting planet of our system. The activity apparent everywhere on his surface, the number and variety of the forms displayed, and the comparative ease with which they may be observed, attest that this object is practically without a rival, and that the investigation of his phenomena is certain to be productive.

The present time is eminently a suitable one for studying his surface markings, and redetermining their proper motions. As the planet's rotation period is less than 10 hours, the times of transit of the same spots may sometimes be obtained twice on one night, for if a marking crosses, say, 3 hours after the planet's rising, the same object will again reach the central meridian about 2⅛ hours before the planet sets.

It is well known that the visible surface of Jupiter consists of a number of light and dark zones interspersed with irregular forms which exhibit great differences in their rates of velocity. Certain white spots, bordering the equator, move very swiftly, and complete a rotation in considerably less time than the red spot. Some dark spots, which have appeared at various times on a double belt about 25° N. latitude, have moved more rapidly still, and shown a rotation in seven minutes less time than the red spot. But it is a peculiar feature of the different markings that they do not maintain the same rate of motion during their existence; in fact, a lengthening of period seems to generally affect them. Thus the red spot in 1880 gave a rotation of 9h. 55m. 34s., while in recent years it has been about 9h. 55m. 41s. The equatorial white spots, which thirteen years ago had a period of 9h. 50m. 6s., have been gradually moderating their speed until in the last few years their period seems to have been 9h. 50m. 30s. It is certain that the various markings are carried along in atmospheric currents, and are subject to remarkable differences, of which we do not comprehend the cause, though we may readily trace the effects.

The red spot situated in Jupiter's S. hemisphere, and on the boundary of the tropical and temperate zones of the planet, is still perceptible, and it is highly probable that the spot existed long before it first came conspicuously into notice in July, 1878. During the last fifteen years there has been little change either in its oval shape or in its dimensions, though its colour and visibility have suffered some trying viscissitudes. It has been successively presented as a brick-red spot, as a faint pink ellipse, as a grey shading, and it is now so feeble that only the outline of its following side can be distinguished, the preceding part of the spot having apparently lost its definite outline. In fact, there seems a prospect of losing the object temporarily if further decadence goes on, but in view of past experience and the probability of recurrence in the Jovian markings, we may certainly expect the spot to reappear, and to present a more conspicuous aspect than it does at the present time.

The following are some eye-estimates of the transits of the spot during the present apparition; they were made by Mr. A. Stanley Williams, of Brighton, and by myself at Bristol:—

Date, 1893.	Red spot at transit. h. m.	Marth's zero meridian. h. m.	Red spot precedes, m.	Observer.
Aug. 9	14 5	14 13·6	8·6	W. F. D.
14	13 15·5	13 22·1	6·6	A. S. W.
16	14 52·2	15 0·6	8·4	,,
16	14 55		5·6	W. F. D.
Sept. 4	15 31	15 41·8	10·8	A. S. W.
14	13 52·2	13 57·5	5·3	,,
Oct. 8	13 35·8	13 43·6	7·8	,,
18	11 50·4	11 58·0	7·6	,,
30	11 45	11 50·0	5·0	,,
Nov. 6	12 29·2	12 34·9	5·7	,,
23	11 25	11 33·9	8·9	W. F. D.

The spot therefore transits a few minutes before the zero meridian based on the daily rate, 870·27° (=9h. 55m. 40·65s. for one rotation), System II. in Mr Marth's ephemerides (*Monthly Notices*, May, 1893).

Mr. Williams writes me that he has recently been able to make out the whole outline of the red spot except the preceding end, and on one very favourable night,

November 6, he glimpsed the spot in its entirety, and describes it as of a pinkish colour. The following and south following part of the spot had quite a dark and definite outline.

On October 31 the red spot was seen with the 16-inch refractor at the Goodsell Observatory, Northfield, U.S.A. It was not a difficult object, though the colour is stated as being very faint. "The S. side of the spot and a belt of similar tint appeared to merge into one another without the slightest change in intensity of colour."

On November 23 I observed the spot with an $8\frac{1}{2}$-inch reflector belonging to my friend, Mr. J. Harvey Jones, of Bristol; but the night was not very good. The red spot was faintly seen, and must have been central at about 11h. 25m. Other details were also noticed as follows:—

A faint, narrow, dark belt, like an irregular pencil-line, on the equator. A similar belt running from about the *p.* end of the red spot to W. limb of the planet. The shouldering of the S. equatorial belt N. of the ends of the red spot was distinctly seen, though that part N. of the *p.* end was very faint. The *f.* shoulder shows a much more gentle slope than formerly. Numerous reddish spots were seen on the N. side of the N. equatorial belt. These were large and conspicuous, as were a series of bright spots *p.* and S. of the red spot. A remarkably brilliant spot on the N. side of N. equatorial belt was central at 10h. exactly.

The general appearance of the planet betokened a more disturbed condition than usual, the belts being full of irregularities.

The great size, durableness, and special character of the red spot have naturally attracted much discussion, and a number of theories have been broached to explain the nature of the spot, and to account for its long endurance. Some writers have regarded it as part of the solid material of Jupiter, but this theory is practically negatived by the fact that it has shown an irregularity of motion. Unless we admit that the rotation period of Jupiter is extremely variable, and has experienced considerable retardation in recent years, we cannot allow that the red spot forms a portion of the sphere. Others believe the spot to represent a condensation of material floating or suspended above the surface of the planet, and that variations of motion and tint are impressed upon it by the action of the Jovian atmosphere, which is constantly in a state of turmoil. Another idea has been mooted to the effect that the spot may possibly be an opening in the atmosphere, through which the surface of Jupiter has been exposed, and that the recent feebleness of the object is occasioned by the filling in of the cavity with highly reflective vapours.

The Rev. E. Ledger remarks that at one time he felt inclined to believe that the permanency of the spot "seemed to indicate that it might be something which, while coagulating or solidifying, in some way caused a gap or break in the cloudy regions above it, or by its cooling condensed the vapours incumbent upon it, and thus increased its own visibility; in fact, that we might be watching in it the gradual formation of a huge continent upon Jupiter."

The theory has also been advanced that the spot was originally formed by ejecta from a volcanic region immediately underlying it, but it must be admitted that no hypothesis appears to be entirely satisfactory in its application, and certainly we cannot regard any one of them as capable of being definitely proved. In a word, it must be avowed that though we have become familiar with the red spot, its motion, shape, and variable tints, during observation extending over more than fifteen years, we are yet far from understanding the mystery it involves. Its production was doubtless the outcome of the energy and activity prevailing above, and possibly on, the planet's surface, but in what particular way the spot was generated it is impossible to say. Nor is the specific date of its first apparition known; it may be a modern resuscitation of the spot which delighted Hooke and Cassini about two centuries ago, or it may only have been initiated into existence just before those memorable nights in July, 1878, when it exhibited an intensely red colour, and struck observers, instantly, as being a most anomalous feature.

But though the spot forms an unsolved mystery, it will continue to be watched with interest by telescopic observers, who will much regret if its present faintness is but the prelude to final dissolution. It can be justly said that no planetary marking visible in modern times has encouraged as much observation, and incited the same amount of interest as the familiar "red spot on Jupiter." Possibly the further study of this remarkable formation may yet enhance our knowledge of the physical condition of the "giant planet," and throw some light upon the singular variations so rife upon his expansive surface.

W. F. DENNING.

THE PREPARATION AND PROPERTIES OF FREE HYDROXYLAMINE.

A CONSIDERABLY improved method of isolating hydroxylamine is described by Prof. Brühl, of Heidelberg, in the current *Berichte*, by which a tolerably large quantity of the pure substance may be prepared without danger in a short space of time, and which may therefore be of general interest on account of its suitability for lecture and demonstration purposes. It may be remembered that M. Lobry de Bruyn, who first isolated solid hydroxylamine two years ago (*vide* NATURE, vol. xlv. p. 20), prepared it from a mixed solution of the hydrochloride and of sodium methylate in methyl alcohol. This solution, after removal of the precipitated common salt, was first concentrated over a water bath, under the diminished pressure of 100 m.m., and afterwards subjected to fractional distillation over a flame at the still lower pressure of 40 m.m. A continuous fractionating vacuum-apparatus was considered unsuitable, and the change of receivers could only be conveniently effected by temporarily arresting the distillation. This mode of operating frequently led to violent explosive decomposition of the heated hydroxylamine, and, moreover, the yield rarely exceeded 17 per cent. of the theoretical. Prof. Brühl, desiring to obtain a considerable quantity of the pure base for spectrometric purposes, has been led to devise the following much more convenient method:—

The methyl alcohol solution is first separated from the precipitated salt, and then immediately transferred to a slightly modified form of the well-known apparatus of Prof. Brühl for fractional distillation *in vacuo*. This apparatus consists essentially of a distilling flask, provided with thermometer and entrance tube furnished with tap, a condenser, and a receiving arrangement which provides for the repeated and rapid change of receiver without impairing the vacuum and without arresting the distillation. This receiving arrangement consists of a short but wide cylinder of stout glass, into which the end of the condensing tube is introduced through a tubulus fitted with bored caoutchouc stopper; inside the cylinder is a circular stand carrying six receiving tubes, which are capable of rotation by means of a rod passing, gas-tight, through a tubulus and its caoutchouc stopper in the top of the cylinder, and terminating in a handle outside. By suitable manipulation of the handle, each of the six receivers may be brought beneath the end of the condensing tube in turn while the distillation is proceeding. The distillation of the methyl alcohol solution contained in the distilling flask is effected by reducing the pressure to the lowest possible amount, and supplying the necessary heat by immersing the flask in a bath of hot water. On

account of the explosive character of hydroxylamine, it is dangerous to employ even a small naked flame, which is liable to effect local superheating. The temperature of explosive decomposition lies in the neighbourhood of 130°; by uninterrupted distillation in the manner indicated, and at a pressure not exceeding 22 m.m., the hydroxylamine passes over entirely at a temperature of 56–57°, and by maintaining the water bath at only a few degrees superior to this temperature all danger of explosion is avoided. The methyl alcohol is practically entirely removed by the pump. Instead of leading the distillate through a warmed condenser, as recommended by M. de Bruyn, a practice which materially diminishes the yield by decomposition of a portion of the product, Prof. Brühl finds it much more advantageous to feed the condenser with a constant supply of iced water; for although the melting point of hydroxylamine is 33°, it does not resolidify even at temperatures only a few degrees above zero, so that stoppage of the condensing tube does not occur. It solidifies instantly, however, in contact with a vessel immersed in ice and salt. The cylinder containing the receivers is therefore immersed in such a mixture, so that each drop of hydroxylamine solidifies the moment it enters the receiver. The hydroxylamine thus obtained in one operation is substantially pure. From thirty grams of the hydrochloride about ten grams of the base may be obtained in one hour, a yield of 66 per cent. of the theoretical, which is four times that obtained by the method of M. de Bruyn. In the case of hydroxylamine becoming a commercial preparation, on account of its extraordinarily great antiseptic power, it would be quite easy, by introducing suitable additional condensers, to recover the whole of the methyl alcohol employed.

The pure white crystalline hydroxylamine melts according to the mode of heating and the size of the containing tube at 32–34°, and its boiling point for a pressure of 22 m.m. is 56–57°. It may actually be cooled below 0° without solidifying, if allowed to remain at rest; but, like most other substances which exhibit the property of superfusion, it solidifies the moment it is agitated. In the solid state it does not appear to be liable to decomposition. Even in the liquid state at 0° indications of decomposition have not been observed. At 10°, however, bubbles commenced to form in the liquid, and at 20° a continuous evolution of gas, mainly nitrogen, occurs, becoming more and more violent as the temperature rises, until sudden explosion takes place. Hence in a warm summer hydroxlamine cannot be preserved in sealed glass tubes. Thus a specimen, after keeping for eight days in July, was found to be no longer capable of solidification even at – 6°, although there was sufficient of the base left undecomposed to explode with a certain amount of violence upon heating, less, however, than in the case of freshly-prepared hydroxylamine. When just prepared one drop warmed in a test tube over a flame explodes with a report equal to that of a gun-shot. It is suggested that hydroxylamine might be safely preserved in metallic vessels, for it appears likely that the notable action of the liquid upon glass causes the commencement of the decomposition.

At the temperature of 23·5° the relative density of pure liquid hydroxylamine is 1·2044. Its refractive index at the same temperature varies from 1·4375 for light of the wave-length of the red lithium line to 1·4514 for light corresponding to the blue hydrogen line $H\gamma$. The substance thus exhibits a small refractive power and a surprisingly small dispersion. Indeed, its molecular dispersion is about the same as was found by Prof. Brühl for nitrogen itself in triethylamine, so that the atom of oxygen and the three atoms of hydrogen would appear to exert no dispersive action if the same value for nitrogen be assumed to be equally operative. The only possible explanation is that the nitrogen here united to oxygen and hydrogen possesses a lower spectrometric constant than when attached to carbon in triethylamine. From a systematic study of the spectrometric constants of the free base, and of the methyl derivative $CH_3NH.OH$ prepared by his assistant Dr. Kjellin, an account of which was given in the Notes of NATURE of November 9, Prof. Brühl has been enabled to prove two important facts. The first is that the constitution of hydroxylamine can be none other than $\genfrac{}{}{0pt}{}{H}{H}\!>\!N-O-H$. The second is that the molecular refraction and dispersion of the nitrogen present in these compounds is the same as that of the nitrogen in ammonia gas, much lower than that of the nitrogen in triethylamine, and that the probable values of these constants of nitrogen linked in this manner, for sodium light, are respectively 2·495 and 0·072. This addition to our knowledge of the spectrometric constants of nitrogen will be of invaluable aid in unravelling the intricate subject of the constitution of the class of nitrogenous organic substances known as "oxims," a subject upon which Prof. Brühl is now concentrating his attention. A. E. TUTTON.

NOTES.

IT is with much regret that we announce the death of Baron von Bülow, at Kiel. Von Bülow's Observatory, better known, perhaps, as Bothkamp Observatory, was the first in Germany devoted to astro-physical researches, and it stands as a splendid monument to his interest in astronomy. By his death astronomical physics has lost one of its most enthusiastic supporters.

THE meeting of the Vienna Academy of Sciences was adjourned on November 16, as an expression of regard for Dr. Alexander von Bach, who died on November 12.

THE memorial to Sir Richard Owen is to take the form of a full-length marble statue, executed by Mr. Thomas Brock, and placed in the Natural History Museum, South Kensington.

A BOTANICAL section has been added to the Zoological Station at Naples, with a small laboratory for algological studies and researches in vegetable physiology.

DR. OSWALD KRUCH has been appointed to the Conservatorship of the Royal Botanical Institute of Rome, recently resigned by Dr. A. Terracciano.

A REUTER'S telegram from Montreal announces that the worst earthquake ever experienced in Canada occurred there at noon on November 27. As far as has been ascertained, no lives were lost, but considerable damage has been done to property, and the walls of many buildings have been cracked.

A SEVERE earthquake was felt at Peshawur, and other places in the Punjab, about nine o'clock on the morning of November 5, but fortunately no very serious damage was done. The wave apparently extended over a large area, including the Tamrud plain and Nowshera.

AN international Photographic Exhibition will take place at Milan from May until October next year. There will be a section for professional photography, another for amateur photography, and a third for technical and industrial applications of photography.

THE Department of Science and Art has received, through the Foreign Office, a dispatch from her Majesty's Minister in Chili calling attention to an exhibition which it is proposed to hold next year at Santiago, dealing with the subjects of mining and metallurgy. The exhibition will be opened in the second

fortnight of April, 1894, but the exact date is not yet known. The eight sections of the exhibition will comprise electricity, mining machinery, mechanical preparation of minerals, metallurgy, chemical industries, statistics and plans, and mining and metallurgical products respectively.

THE Municipal Council of Lausanne has been considering a scheme for the electrical transmission of power (says *La Nature*). It is proposed to obtain work to the extent of about 1200 horse-power from the Grand-Eau river, at a distance of forty kilometres from Lausanne This energy will be utilised to supply about 5000 lamps and 16 arc-lights during the night, while in the day it will furnish the motive power for electric trams, and motors for domestic use, besides pumping the town's water-supply to the proper level.

THE new examination laboratories of the Institute of Chemistry will be opened on Friday, December 8.

THE last of the Gilchrist lectures, in connection with the Bethnal Green Free Library, will be given on Thursday, December 7, by Dr. Andrew Wilson, on "Brain and Nerve and their Work."

PROF. BORNMÜLLER has returned from his extended botanical journey in Persia.

A COMMITTEE has been appointed by the Italian Botanical Society for the study of the flora of Italy, both phanerogamic and cryptogamic. The reports from the various members will be collated by Prof. Arcangeli, and published in the *Bulletino* of the Society.

Bulletin No. 38 of the Experiment Station of the Kansas State Agricultural College is occupied by a preliminary report on rusts of grain, accompanied by three plates illustrating the mode of development of *Puccinia graminis*, *P. rubigo-vera*, and *P. coronata*. In Kansas the two former of these are found chiefly on wheat, while the last is apparently confined to oats.

EVIDENCES of the existence of man in Nicaragua during the early Neolithic age were discovered by the Spaniards about the beginning of the sixteenth century. They mainly consist of flint-heads of arrows and spears, stone statues of men, and numerous fragments of pottery made of clay, containing fragments of volcanic rocks, unadorned and originally unburned. Of these evidences, those indicating the geological time or epoch in which they were made are, according to Mr. J. Crawford (Proceedings of the Boston Society of Natural History, vol. xxvi. p. 49, 1893): (1) Several well-executed stone statues found in the same locality, and all of the same brachycephalic type, carefully sculptured from blocks of hard rock, with brittle tools of flint, jasper, and felsite; (2) oblong blocks of partly metamorphosed rocks, in their natural state or but slightly shaped by man, apparently forming the foundations for an oblong temple or observatory extending east and west; (3) fragments of unadorned pottery found near the stone images, cemented in the débris of a well-marked subsidence, all discovered in the small valley on the west face of the mountain island of Momotombito. This island is situated near the volcanic cone Momotombo, and an unobstructed view of the Pacific Ocean, about twenty-seven miles to the westward, can be obtained from the observatory or temple. Mr. Crawford's examination of the locality and the handiwork leads him to believe that "the aborigines of the sculptors of the stone images found on the island came from Polynesia, over the land route or chain of almost connected islands then existing across the Pacific Ocean, and that the latest subsidence of twenty-five feet, as recorded on the island and the western part of Nicaragua, and the consequent synchronous activity of all the volcanoes in that region, both occurring during the time when the sculptors were carving stones into images of types of their own people, caused the sculptors and their tribe to migrate eastward (the only safe route) and seek a home on the side of the very fertile and non-volcanic Amerrique mountains, where their probable descendants—the Amerriques—now reside."

THE first of the three articles in the current number of the *Internationales Archiv für Ethnographie* (vi. parts 4 and 5) is by Prof. H. H. Giglioli. It is entitled "Notes on the Ethnographical Collections formed by Dr. Elio Modigliani during his recent Explorations in Central Sumatra and Engano." Dr. Modigliani published in 1890 a valuable book, "Un Viaggis a Nias," giving an account of his anthropological investigations in that little known island. Giglioli's communication, which is fully illustrated, appears to be a preliminary notice of a forthcoming work by Modigliani, and it gives to English readers a foretaste of the extremely interesting and important investigations made by that skilled observer and excellent collector. Modigliani was not allowed by the Dutch colonial authorities to remain long among their foes the Battaks of Lake Toba, but he made good use of his time, and also discovered a magnificent waterfall. Giglioli gives an admirable summary of the arts and crafts, habits and superstitions of these literally cannibals. The islanders of Engano remarkably resemble the Nicobarese, but the faces of some of them recall Polynesian and especially Micronesian types. Like other islands, the old order is rapidly changing, and the population of about 8,000, ten years ago, is now reduced to 840. Prof. A. C. Haddon has a paper on "The Secular and Ceremonial Dances of Torres Straits," illustrated by woodcuts and four admirably executed coloured plates. This is the first time that any Papuan dances have been adequately described. The dances are classified into festive dances, war dances, ceremonial dances (including initiation and seasonal dances), turtle processions, and funeral ceremonies. The descriptions of the dances and the decoration of the performers are given in great detail; the initiation and funeral ceremonies were carefully built up, so to speak, from the accounts of the natives. Here also so much change has taken place, that in a short time it will be impossible to gather any further information of any value. Prof. W. Joest has an illustrated paper on various toys ("Allerlei Spielzeug"). There are also the usual notes, reviews, and bibliography.

WE have received from Sgr. Arcidiacono a pamphlet containing the results of observations of the geodynamic phenomena which preceded, accompanied, and followed the Etna eruptions of May and June, 1886, carried out under the direction of the late Prof. Orazio Silvestri, of the University of Catania. This work forms a valuable addition to geodynamic literature, and contains a detailed account of the movements, both microscopic and sensible, observed in the various seismological stations around Etna from May 18 to June 11, a table of all the shocks recorded, with their general character, direction, and intensity, and a reproduction of the seismograph diagram in the form of a curve about 15 feet long, which shows the course of the phenomena as recorded between the dates May 8 and June 16. The general aspect of calm was first broken on May 12, where slight and slow perturbations are recorded. These were repeated more emphatically on May 14 and 15. The 17th was calm, but at 10.30 a.m. on the 18th the explosion of the central crater occurred, which threw the barometer stile right off the scale. This was followed by a continued succession of violent shocks during the same day, and by the eccentric explosion of the southern flank on May 19. The eruption then followed a regular course until May 26, the disturbances being much smaller and of nearly constant average amplitude for each hour. A steady diminution of the eruptive

force took place until May 31. This and the following day were visited by two considerable shocks, followed by another strong concussion on June 5, which marked the close of the eccentric eruption. The 9th witnessed some disturbances accompanying a mild eruption of the central crater, and calm was finally re-established on June 14. A coincidence worth noticing is that of the highest barometric pressure observed during all that time, a pressure of 771 mm., with that of the great central eruption on May 18. The greatest disturbances were produced along a line passing through the focus in a direction from east-north-east to west-south-west, this being at right angles to a radial line which was the seat of the 1883 eruption.

Measurements of the amount of light absorbed by thin metallic films of various thicknesses are incapable of affording a true measure of the absorptive power of these films unless the films compared have the same reflecting power at normal incidence. M. Salvador Bloch has been for some time experimenting with collodion films coloured with fuchsine, and thus made to exhibit a metallic aspect. According to an account published in the *Comptes Rendus*, he has succeeded in obtaining films of different thicknesses and of equal reflecting powers. Two pellicles formed by pouring layers of different thickness over glass plates, and evaporating under the same conditions, show, if all goes well, a strong resemblance as to reflecting powers. This was tested by studying with a Babinet compensator the ellipticity of the green rays near the E line reflected from the pellicle. The employment of sunlight enabled the observer to measure differences of phase down to $\frac{1}{250}$ of a wave-length. For two such pellicles no difference of phase exceeding or even approaching that limit was observed in any portion of the films. Three such films, called A, B, and C, and of thicknesses 1744, 1921, and 1964$\mu\mu$, respectively, were used for determining the index of absorption for the yellow D rays. The index of absorption was taken as defined by the fact that a vibration progressing in the absorbing medium through a length $\frac{\lambda}{2\pi}$ has its amplitude reduced in the ratio $1 : e^{-\gamma}$, where γ is the index of absorption. From A and C combined, γ was found to be 0·088, and from A and B 0·084. Films of such thickness were opaque to green, but another set of films, of thicknesses 353, 504, and 627$\mu\mu$, respectively, were found thin enough for measurements in the case of green light. The two corresponding values found were 0·529 and 0·505. The spectrophotometer used was analogous to a half shadow polarimeter. A polarised beam of sunlight fell normally upon a biquartz. The light then passed through an analyser with divided circle, and then through a lens, which projected an image of the biquartz upon the slit of a spectroscope provided with an eye-slit. The spectrum then consisted of two superposed portions, each corresponding to one of the quartz plates. The film was then cut half off the glass, and placed so that the edge coincided with the junction of the biquartz, with the result that the light suffering absorption passed through one of the quartzes only. Equality was established by turning the analyser. A special advantage of this arrangement is that it requires only one source of light.

There exist at present numerous arrangements for "turning down" an electric light, the chief peculiarity of them all being that nearly as much electrical energy is consumed when the lamp is only glowing feebly as when it is giving its normal amount of light. An arrangement to which this objection does not apply is described in the Proceedings of the American Institute of Electrical Engineers for September, by Mr. F. Moore. In the circuit of the lamp there is placed an automatic interrupter, consisting of a small electromagnet and an armature held back by a spring; the contacts being so arranged that as the armature vibrates the current is interrupted during part of the oscillation. By this means different amounts of current can be passed through the lamp, for by moving the electromagnet nearer to or further from the armature, the speed with which the latter vibrates can be varied. To avoid the destructive effect of the sparks at the contacts the whole armature is enclosed in a glass globe from which the air has been exhausted. Under these conditions it is found that platinum contacts remain good for a considerable time. When the interrupter is at work the sparks produce in the exhausted globe a phosphorescent glow which the author thinks may possibly be made use of for the purpose of giving light. Another application of the above is for running lamps on circuits of much higher voltage than they are intended for.

Wiedemann's Annalen der Physik und Chemie for November contains an interesting paper by R. Hennig, on the magnetic susceptibility of oxygen. The method employed, namely, the measurement of the displacement in a magnetic field of a short column of liquid in a slightly inclined capillary tube, due to the difference in the susceptibility of the two gases (oxygen and air) at the two ends of the liquid column, would hardly seem at first sight capable of giving very accurate values. The author, however, has obtained very fairly consistent results, and finds the value $0·0963 \times 10^{-6}$ for the difference between the susceptibility of oxygen and air at a temperature of about 26° C., and at pressures varying from 75 cm. of mercury to 328 cm. In order to measure the strength of the magnetic field a small coil was suspended by a bifilar-suspension close to the capillary tube, and from the deflection, when a known current was passed through this coil, the strength of the field was calculated. The results obtained by this method were also compared with those found by the rotation of polarised light in a piece of heavy glass, and by means of a small induction coil which could be rapidly moved out of the field.

Some interesting investigations on the vitality of the cholera organisms on tobacco have been made by Wernicke (*Hygien: Rundschau*, 1892, No. 21). Small pieces of linen soaked in cholera broth-cultures were rolled up in various kinds of tobacco, and the latter made into cigars. At the end of twenty-four hours only a few bacilli were found on the linen, and none on the leaf. On sterile and dry tobacco leaves, the bacilli disappeared in one-half to three hours after inoculation. On moist, unsterilised leaves they disappeared in from one to three days, but on moist and sterile leaves in from two to four days. When introduced into a five per cent. tobacco infusion (10 grams of leaves to 200 grams of water), however, they retained their vitality up to thirty-three days; but in a more concentrated infusion (one gram of leaves to two grams of water, they succumbed in twenty-four hours. When enveloped in tobacco smoke, they were destroyed, both in broth-cultures as well as in sterilised and unsterilised saliva, in five minutes. Tassinari, in his paper, "Azione del fumo di tabacco sopra alcuni microrganismi patogeni" (*Annali deli Istituto d'Igiene*, Rome, vol. i., 1891), describes a series of experiments in which he prepared broth-cultures of different pathogenic microbes, and conducted through them the smoke from various kinds of tobacco. Out of twenty-three separate investigations, in only three were the cholera organisms alive after thirty minutes' exposure to tobacco fumes. But in actual experience the apparent antiseptic properties of tobacco have not unfrequently been met with; thus, during the influenza epidemic in 1889, Visalli (*Gazetta degli Ospedali*, 1889) mentions the remarkable immunity from this disease which characterised the operatives in tobacco manufactories; that in Genoa, for example, out of 1200 workpeople thus engaged, not one was attacked; whilst in Rome the number was so insignificant that the works were never stopped, and no precautions were considered necessary.

THE *Deutsche Seewarte* has published No. xi. of the results of observations taken in the North Atlantic on ships supplied with instruments either belonging to that institution, or verified by it. Each part contains all the observations made in a ten-degree square, which is again subdivided into 100 one-degree squares, grouped in such a way that anyone can make use of them as they are, or they can be eventually combined with the observations made by any other institution. The tract now covered by these volumes extends from latitude 20°–50° N., and longitude 10°–50° west (with the exception of one square), and this district joins on to that for which the data were discussed some years ago by the Meteorological Council, and extending from 20° N. to 10° S. latitude; so that for nearly all that part of the North Atlantic which is traversed by long-voyage ships a large amount of useful data is available, either for scientific inquiry or for the purpose of navigation. The winds are tabulated under sixteen points, and storms under four quadrants, while the mean values of pressure, temperature, &c., are deduced from the total number of observations in each sub-square. This work is quite independent of the synoptic weather charts of the North Atlantic, which are regularly prepared by the Seewarte, in conjunction with the Danish Meteorological Institute.

THE *Kansas University Quarterly*, vol. ii. No. 2, contains three articles by Prof. S. W. Williston. In one of these, entitled "Kansas Pterodactyls," a previous article is referred to, in which the opinion was expressed that the genus *Pteranodon* occurs in Europe. Since then Prof. Williston has seen papers by Prof. Seeley, in which the same view is held, and an attentive examination of the evidence leads him to say: "I am satisfied that there can no longer be any reasonable doubt of the congenerousness of our species with those included in the genus *Ornithostoma*. Seeley, a generic name antedating *Pteranodon* Marsh by some five years."

MR. R. L. JACK, the Government Geologist at Brisbane, has prepared a report on the progress of the geological survey of Queensland during 1892. Attention has been confined to detailed mapping of small areas of economical importance. For a general colony map it is thought that the scale of sixteen miles to an inch permits sufficient detail to be shown. As visiting the different mines will occupy some considerable time, it is intended to publish, in the meantime, a map showing the geological features, which will also be useful in the hands of miners and the general public for its topography. On the map, which is now being drawn on stone, are shown the outcrops of most of the reefs, as at present understood. A subsequent edition will show the actual or inferred outcrops of all the reefs, the underground workings, and the geological information acquired in the course of the underground survey by the Geological Staff. On the completion of the work, it is in contemplation to construct a glass model, the surface of which will be coloured, and the outcrops of the reefs shown in the same way as in the geological map, and the extension of underground geological boundaries, so far as ascertained, will be represented. Its main advantage, however, will be that the exact position of the reefs with relation to the surface features and artificial boundaries will be understood at a glance, and the depth at which any given reef would be met with in any position could be ascertained by a simple calculation.

A PAPER read by Dr. V. Ball, before the Royal Irish Academy on January 23 of this year, has been reprinted from the "Proceedings" (3rd Ser. vol. iii. No. 1, pp. 151–169). The title is "On the Volcanoes and Hot Springs of India, and the Folk-Lore connected therewith." Dr. Ball shows how the evidences of past volcanic activity in India—the metamorphism of sedimentary rocks by the Deccan traps into porcellanic shales, the agates, cornelians, &c. produced, the peculiar appearance of old craters, the "Lonar Lake," the natural caves and pillared temples of basaltic rock, &c.—have formed a nucleus of truth around which the religious spirit of the people has wrapped coil upon coil of myth and the marvellous. Sometimes undue credence has been given by travellers to native tales of smoke emanating in present times from peaks in Western Bengal and the Central Provinces. For these no better foundation could be discovered by Dr. Ball than the ordinary atmospheric effects of mist and cloud. Bhawani Patna, in the Central Provinces, is an example of a "mythical volcano." Hot springs have more especially appealed to the superstition of the people, and served the purposes of the native priesthood. Dr. Ball stated that the total number of recorded sites where hot springs occur in India is about 300. He gave then a concise account of the most important scientific phenomena associated with the hot springs, and details, in some cases, of the particular virtues, medical and spiritual, ascribed to them by the people. He called attention, in concluding, to the local character of the vegetation near hot springs, and of the fauna which are sometimes present in their waters, *e.g.* the famous Magar Pir, seven miles north of Karachi, with its numerous crocodiles.

THE August number of the *Records of the Geological Survey of India*, vol. xxvi. part 3, has been sent us. An important paper is the "Geology of the Sherani Hills," by Mr. T. D. La Touche, with a geological map of part of the Sulaiman Range and several sections and sketches (pl. i.–v.). The first part of the paper is devoted to the physical features. The stratigraphical geology of the Sherani Hills is not complicated; the deposits in the area examined range from Cretaceous to recent and sub-recent time, and a complete table of the succession and the relative thicknesses of the rocks is given on p. 82. Dr. Fritz Noetling describes "Carboniferous Fossils from Tenasserim"; good specimens of *Lonsdaleia salinaria*, and new species of Lithostrotion and of Schwagerina are figured on the accompanying plate. Details are given by Mr. R. D. Oldham, Superintendent Geological Survey of India, of a deep boring at Chandernagore, and a "Note on Granite in the Districts of Tavoy and Mergui" (with plate), by P. N. Bose. Especial comment is made in the "Tri-Monthly Notes of the Geological Survey of India Department" upon the completion of the second edition of the "Manual of the Geology of India," by Mr. Oldham.

THE calendar for the year 1893–4 of the University College of North Wales has just been issued.

WE note with pleasure that the Oxford University Press has published two more editions of the "Oxford Bible for Teachers," containing the excellent "Helps to the Study of the Bible" reviewed in NATURE of October 5.

WE have received a "Record" of results of observations in meteorology and terrestrial magnetism made at the Melbourne Observatory and at other localities in the colony of Victoria, Australia, from July to December, 1892, under the superintendence of Mr. R. L. J. Ellery, the Government Astronomer. In the future this "Record" will be issued quarterly instead of monthly.

MESSRS. WILLIAM WESLEY AND SON have issued their 118th "Natural History and Scientific Book Circular." The catalogue includes a number of works from the library of the late Sir G. B. Airy, in addition to transactions of scientific societies, periodicals and serials, Government reports, and works dealing with the history of science. It should be in the hands of every bibliophile.

THE sixth edition of a book known to most chemists, viz. "Laboratory Teaching," by the late Prof. C. L. Bloxam, has

been published by Messrs. J. and A. Churchill. Mr. A. G. Bloxam, the editor of the new edition, has made several important additions and alterations, and these changes will doubtless enable the book to retain its high position among the many works that now exist on practical chemistry.

WHAT are happily termed "Drum-and-trumpet Histories" have not been so numerous since the publication of the late Mr. Green's famous narration of the development of the English people. A more pretentious work of a similar kind is "Social England," edited by Dr. H. D. Traill, and published by Messrs. Cassell and Co. In this history a section of each epoch is devoted to a description of the conditions of science and learning, and another to trade and industry. The departure cannot be too highly commended, for the truest epic of a nation's life is that in which the interests of all classes are recited.

LANTERNISTS will be glad to learn that Messrs. Perken, Son and Rayment have introduced a new oil-lamp, possessing three times the candle-power of those hitherto used for lantern projection. This gain of brilliancy is obtained by dividing the oil reservoir, so as to provide central air-shaft. The combustion is thus rendered more perfect, and the odour that usually accompanies ordinary lamps is correspondingly decreased. For small audiences the lamp will suit a lecturer's purpose quite as well as the lime-light. Doubtless the recent fatal result of the breaking of an oxygen cylinder at Bradford will considerably increase the demand for perfected lamps of this kind.

THE success of Sir John Lubbock's book on "The Beauties of Nature" has induced Messrs. Macmillan to issue a cheap edition, without illustrations. Though the book possesses a good table of contents, its value would be increased by the addition of an index. The author will be glad to have his attention called to one or two slips. On p. 207, Jupiter is said to have *four* satellites, whereas Prof. Barnard's discovery has brought the number up to five. Nitrogen should be removed from the list of elements in comets (p. 213), and *Clarke* (p. 223) should be Clerke. These slips, however, are but spots on the sun, for there are few books that will enlighten the general reader more than the one before us.

A REMARKABLE new substance, isocyanogen tetrabromide, $Br_2C=N-N=CBr_2$, has been obtained by Dr. Thiele in the laboratory of the Munich Academy of Sciences, and an account of it is contributed to the current *Berichte*. It was prepared by the reduction of azotetrazine, a new substance very rich in nitrogen (concerning which Dr. Thiele promises a further communication), and by treatment of the reduction product, hydrazotetrazine, with bromine. Isocyanogen tetrabromide is readily volatile in steam, insoluble in water, but soluble in organic solvents, particularly in ether. It crystallises from glacial acetic acid in large prisms, which rapidly lose their brilliancy, however, upon removal from the mother-liquor. The crystals melt at 42°, emitting a most pungent, irritating odour. The crystals normally in the cold evolve the same odour, although not so strongly as when warmed. Concentrated sulphuric acid, at the temperature of a water-bath, rapidly dissolves them with production of hydrazine and evolution of carbon dioxide, hydrobromic acid, and smaller quantities of free bromine and sulphur dioxide. Water precipitates from this solution a large quantity of hydrazine sulphate, which may easily be identified by its melting-point (256°), its reduction of silver solutions, and its formation of a difficultly soluble double sulphate with copper sulphate. The reaction for the decomposition by sulphuric acid is probably as follows:

$$Br_2C=N-N=CBr_2+4H_2O=4HBr+2CO_2+N_2H_4.$$

Dilute hydrochloric and sulphuric acids only attack the tetrabromide after long-continued heating to 300°, the former then converting it into nitrogen and ammonia, and the latter oxidising it. Its reaction with alkalies is specially interesting. It dissolves readily in them, and upon subjecting the alkaline liquid to distillation another new compound, which is probably isocyanogen oxide $OC=N-N=CO$ or a polymer of that substance, passes over with the last portion of distillate. If a reducing agent, such as alcohol, a ferrous, manganous or stannous salt, is added to the alkaline solution, a powerful odour of the well-known isonitrile kind is at once emitted. This same odour is produced when the alcoholic solution of the tetrabromide is decomposed with zinc dust and a little chloride of zinc. It appears most probable that the odour is due to the hitherto unisolated isocyanogen, $C=N-N=C$. The supposition is further justified by the fact that the strongly odourous substance is expelled by boiling in a current of carbon dioxide, and is capable of absorption by hot dilute sulphuric acid with formation of a solution of just such powerfully reducing proclivities as might be expected from a solution of hydrazine and formic acid.

THE first results of an important research in connection with the melting-points of the more refractory inorganic salts are likewise communicated to the current *Berichte* by Prof. Victor Meyer and Dr. Riddle. The observations have been made with the object of ascertaining the relations of the melting-points of definitely connected salts, those already investigated being the chlorides, bromides, and iodides of sodium and potassium, and the sulphates of those metals. The method adopted in order to measure such high temperatures with accuracy was essentially as follows:—The salt was heated considerably above its melting-point in a capacious platinum crucible, by means of a Perrot furnace. The crucible was then removed from the furnace, and an air thermometer, constructed of platinum and on the compensating principle, was inserted into the liquid salt. As soon as solidification of the latter commenced the temperature remained constant for some little time, quite sufficient to enable the air, or in the cases of very high melting-points, the nitrogen contained in the thermometer, to be displaced by hydrochloric acid gas, and its volume measured over water. The results obtained are the following:—The chloride, bromide, and iodide of sodium melt at 851°, 727°, and 650°, respectively; the analogous salts of potassium fuse at 766°, 715°, and 623°. In each case a lowering of the melting-point accompanies the increase of the atomic weight either of the halogen or of the metallic element. Potash (presumably the oxide) melts at 1045°, and soda at 1098°, the same rule again applying. In the cases of the sulphates, however, sodium sulphate is found to melt at 843°, and potassium sulphate at the much higher temperature of 1073°, a result contrary to the rule for the halogen salts, but which is quite in keeping with other well-known differences which the oxy-salts of sodium and potassium exhibit.

THE additions to the Zoological Society's Gardens during the past week include a Chacma Baboon (*Cynocephalus porcarius*, ♂) from South Africa, presented by Mr. W. S. Cox; two Common Marmosets (*Hapale jacchus*) from Brazil, presented by Dr. S. Steggall; a Pallas' Goat (*Capra cylindricornis*, ♀) from the Caucasus Mountains, presented by Mr. H. H. P. Deasy; a Duyker Bok (*Cephalophus mergens*, ♂) from South Africa, presented by Miss Gertrude A. Winly; three Palm Squirrels (*Sciurus palmarum*) from India, presented by Mrs. S. W. MacIver; a Meyer's Parrot (*Pæocephalus meyeri*) from South Africa, presented by Mrs. B. Searelle; a Great Eagle Owl (*Bubo maximus*) from China, presented by Major Boyd Bredon; two Puffins (*Fratercula arctica*) British, presented by Mr. E. Hamond; a Brown Capuchin (*Cebus fatuellus*, ♂) from Brazil, a Rhesus Monkey (*Macacus rhesus*, ♀) from India, six Meyer's Parrots (*Pæocephalus meyeri*), an Alario Sparrow (*Passer alario*) from South Africa, deposited; two Redshanks (*Totanus calidris*), British, purchased.

OUR ASTRONOMICAL COLUMN.

OTTO STRUVE'S DOUBLE-STAR MEASURES.—The most important addition to double-star astronomy during the last year is without doubt the work which we owe to Otto Struve, and which is entitled "Mesures Micrométriques des Étoiles Doubles" (Observations de Poulkova Tome IX. (avec un supplement) et Tome X.). The period which the observations cover is very large when one considers that it is for one observer, commencing as it does with the observations made in the year 1837, when Otto Struve was only seventeen years old. Readers who are unable to approach these volumes themselves will find that M. Bigourdan, in the October number of the *Bulletin Astronomique*, gives a general summary of the whole of the contents. As one would expect, the introductions to the volumes contain a mine of important information, both with regard to the measures and to the puzzling question of the "personal equation," a question on which even to-day astronomers hold different views. Otto Struve busied himself especially in this direction, making, in the years 1853-1876, a series of measures of artificial double stars. The expressions for the corrections which he obtained assumed considerable proportions, as will be seen below, the first being that for angles of position, and the second that for distance :—

Position angle

$$\text{Corr.} = + \frac{5^\circ{\cdot}2}{1 + 0{\cdot}20g^2} + \frac{4^\circ{\cdot}4 \sin(2\phi - 27^\circ\ 13')}{1 + 0{\cdot}14(3{\cdot}3 - g)^2} + \frac{5^\circ{\cdot}6 \sin(4\phi - 25^\circ\ 0')}{1 + 0{\cdot}20g^2}.$$

Distance

$$\text{Corr.} = + \frac{0''{\cdot}050(g - 2{\cdot}0)}{1 + 0{\cdot}09(4{\cdot}2 - g)^2} + \frac{0''{\cdot}15 \cos(2\phi - 28{\cdot}4)}{1 + 0{\cdot}06(5{\cdot}2 - g)^2}.$$

when g represents "l'angle visuel du couple considéré experimé en prenant pour unité celui qui correspond au grossessement de 708 fois," and ϕ is the angle of the line between the two stars and the vertical.

Whether such corrections as these, made under non-observational conditions, should be applied to measures actually made in the sky is still open to much doubt. Otto Struve discusses also the observations made at Pulkova with those made at the same epoch by different observers; the comparison, to take an example, shows that Dawes's position angles in his early measures appear free from systematic error, while those made later require a correction of $+ 1^\circ{\cdot}8$; his distances up to 8″ seemed all to be desired. Dembowski's measurements of angles also required no correction, but his distances, especially about 6″, demand a small positive correction (0″22). In the second volume one finds the measures of W. Herschel's classes V. and VI., couples with large proper motion, including measures for the determination of parallaxes, and for the determination of the relation of the number of optical to physical binary, stars discovered by M. Burnham and other astronomers, and a continuation of W. Struve's and O. Struve's measures. Double-star astronomy is already possessed of two fine monuments in the works of W. Struve's "Mensuræ Micrometricæ" and of Baron Dembowski's "Misure Micrometriche," and to-day we may, as M. Bigourdan adds, name a third in the "Mesures Micrométriques des Étoiles Doubles" of M. Otto Struve.

METHOD OF PIVOT TESTING.—By means of interference fringes, employed by M. Fizeau in his researches on crystals, M. Maurice Hamy describes a method of studying the form of pivots of a meridian instrument (*Comptes Rendus*, No. 20, Nov. 13th), which indicates errors not discernible by the ordinary course adopted. The great advantage to be gained by it is that the state of the pivots can be very easily, and with the expenditure of a very little time, ascertained. The arrangement consists in placing a metallic block astride a pivot, the block being supported further by a pointer fixed to a part of the telescope. The extremity of this pointer fits into the bottom of a horizontal groove, parallel to the meridian, in the pier. Contacts between the pivot and the pointer is thus ensured by the pressure of several weights, while displacements of the whole arrangement against slipping are totally eliminated. On the block rests, at one of its extremities above the centre of the pivot, a lever which is movable about an axis on the pillar on a vertical plane; this carries a small horizontal piece of glass, fixed in a certain manner. Between this mirror and the front of the lens of a fixed collimator are produced the interference fringes, the source of light (monochromatic) being placed at the focus of the lens. Turning the telescope on its axis, the block remains still, but movements of a small nature in the vertical direction were observed which were sufficient to indicate the imperfectness of the pivot. To obtain at a glance the order of the magnitude of such errors, a plane mirror was fixed at some distance from the axis of the lever, so determined that the fringes were displaced by a row when the inclination of the telescope experienced a perturbation of 0·01s. by the action of one of the irregularities. The method of observation consists simply in counting the number of fringes which exceed a fixed limit when the telescope is turned, the number thus obtained expressing in hundredths of a second in time the order of the error. A trial of the above method shows that irregularities on the surface of pivots can be easily observed, and, moreover, the errors "ne sont pas complètement négligeable au point de vue des observations."

A BRIGHT METEOR.—The following are a few facts about a bright meteor which Prof. Schur, of Göttingen, has been good enough to send us:—The meteor was observed on Monday, November 27, at 5h. 54m. mean time, and the direction of its path lay between ζ Perseii and towards α Piscium. At first it appeared as bright as α Tauri, and then quickly excelled Jupiter in brilliancy, the light gradually fading away afterwards. The duration of the phenomenon was estimated at about ten seconds, and the trail was observed to be of a yellowish-red colour. Curiously enough, three minutes later a fainter meteor shot across the heavens from the zenith, its direction being nearly at right angles to that of the preceding one.

ASTRONOMICAL PHOTOGRAPHY.—Mr. H. C. Russell, F.R.S., President of the Astronomy, Mathematics, and Physics Section of the Australasian Association for the Advancement of Science, traced the history of astronomical photography in his presidential address at the recent Adelaide meeting. "In many departments of astronomy," he declared in the opening paragraph, "the observer must stand aside while photography takes his place and works with a power of which he is not capable, and I feel sure that in a very few years the observer will be displaced altogether, while his duty will be done by a new sensitive being—a being not subject to fatigue, to east winds, to temper, and to bias, but one above all these weaknesses, calm and unruffled; with all the world shut out, and living only to catch the fleeting rays of light, and tell their story."

"VIERTELJAHRSCHRIFT DER ASTRONOMISCHEN GESELLSCHAFT."—The third part of this year's publication gives an account of the work done at the observatories usually included in this list, each director, as has been done in former numbers, summing up in a few words, and stating the work being, and about to be, accomplished. We must refer our readers to the publication itself for individual information.

GEOGRAPHICAL NOTES.

L'Afrique gives a brief account of the last exploring journey of the late M. Georges Muller in Madagascar. He had returned to Antananarivo from a successful visit to Antsirabe, where he went to collect bones of *epiornis*, and in June he set out for Lake Alaotra, which, in company with Father Roblet, he explored, adding a number of features to the maps of the district. Parting from his companion, Muller pushed on with the view of reaching Mojanga on the west coast, but near Mandritsara he was attacked and murdered by a party of Fahavalos, one of the independent tribes who still contend against the Hova supremacy of the island.

THE *Madras Mail* says that the Indian Marine Survey vessel *Investigator* has proceeded to the Laccadives to continue the survey of those islands, which has been in course of preparation during the last two years. From the Laccadives the *Investigator* will go to Madras, and will be engaged for a few weeks in completing the East Coast Marine Survey from Pulicat Lake, where work was left off last year, to Madras Harbour. Finally in February the *Investigator* will proceed to Palk Straits, and a thorough survey of the dividing sea between India and Ceylon will be made, ostensibly with the object of testing the practicability of constructing a canal and a railway. The distance from the Indian mainland to Ceylon is sixty miles, of which twenty constitute Adam's Bridge proper. The bridge is said to consist of an irregular ridge formed of rock and sand partly dry at low water, but intersected by small intricate channels navigable only for native boats of very light draught. Average

spring tides rise only about two feet, so that the construction of the railway works and their future maintenance would be greatly facilitated. It is thought that the works required would consist of an iron and steel viaduct of considerable length, but in short spans, no large span being required except over the existing navigable channel, where a swing bridge would probably be necessary. Until a detailed survey of the strait has been made, however, it is impossible to speculate upon the details of the railway or the canal project with any degree of certainty; and the Government of India is determined to settle the question once for all by making a thorough survey of the coast and dividing sea.

FULL particulars have lately been received of the death by drowning, in September last, of Mr. H. M. Becher, while on his way to visit the mountain known as Gunong Tahan in the province of Trengganu in the Malay peninsula. He had come within sight of the mountain, which had never before been seen by a European, and roughly estimated its height at between 8,000 and 9,000 feet, when his camp on a low island in a river was submerged by a sudden flood, and the boat in which he attempted to reach the shore capsized. His companion, Mr. H. Quin, escaped, but did not continue the journey.

A LONG letter just received from Mr. Astor Chanler, who is travelling in East Africa, is published in the December number of the *Geographical Journal*. It contains the unfortunate tidings that his companion, Lieutenant von Höhnel, whose previous successful travels in East Africa are well known, had been seriously wounded by a rhinoceros, which rendered his immediate return to Europe necessary. Mr. Chanler, although he has suffered greatly from loss of men and animals, is determined to push on to the north in the hope of reaching Berbera or Zeïla. At the time of writing, September 20, the party had returned to Daicho, near Mount Kenia, after a visit to the Rendile tribe, who live in the country to the north. These people appear to have strong Somali affinities, and were more intelligent than the Masai, but equally fierce and intractable. The loss of von Höhnel's services will detract from the geographical value of the expedition, as he is an accomplished surveyor.

IN our last issue we gave, without comment, an abstract of one of the rumours regarding the Nansen expedition, published by an evening newspaper. It is right to add, however, that the report of high land north of the New Siberian Islands is no new thing, and that Nansen has no thought of taking up winter quarters on any land, his intention being to get fast in the ice, and drift wherever it carries him. His only object in touching at the New Siberian Islands was to send letters home; but if the sea was as favourable as we believe it to have been, he would probably strike straight northward without calling anywhere.

ANTARCTIC EXPLORATION.

AT the meeting of the Royal Geographical Society on Monday evening Dr. John Murray, of the *Challenger* Expedition, read a paper on the renewal of Antarctic exploration. He sketched the history of voyages to the far south, and of the notions which prevailed as to the nature of the South Polar region from the earliest time down to the present day. He showed that while the huge southern continent believed in by the geographers of past ages had been vastly diminished by increased knowledge, the probability is that around the South Pole a land area of about 4,000,000 square miles actually exists. He indicated the present state of our knowledge of the region, which is extremely meagre, and then went on to show that until this knowledge was greatly increased many problems in science must remain unsolved. Until we had a complete and continued series of observations in the Antarctic area the meteorology of the globe could not be understood. Important problems in geology, in biology, in physics, in oceanography, demanded the renewal of research on an adequate scale in the South Polar area. Dr. Murray concluded as follows:—

Within the past few months I have been in communication with geographers and scientific men in many parts of the world, and there is complete unanimity as to the desirability, nay, necessity for South Polar exploration, and wonder is expressed that an expedition has not long since been fitted out to undertake investigations which, it is admitted on all sides, would be of the greatest value in the progress of so many branches of natural knowledge.

To determine the nature and extent of the Antarctic continent; to penetrate into the interior; to ascertain the depth and nature of the ice-cap; to observe the character of the underlying rocks and their fossils; to take magnetic and meteorological observations both at sea and on land; to observe the temperature of the ocean at all depths and seasons of the year; to take pendulum observations on land, and possibly also at great depths in the ocean; to bore through the deposits on the floor of the ocean at certain points to ascertain the condition of the deeper layers; to sound, trawl, and dredge, and study the character and distribution of marine organisms. All this should be the work of a modern Antarctic expedition. For the more definite determination of the distribution of land and water on our planet; for the solution of many problems concerning the Ice Age; for the better determination of the internal constitution and superficial form of the earth; for a more complete knowledge of the laws which govern the motions of the atmosphere and hydrosphere; for more trustworthy indications as to the origin of terrestrial and marine plants and animals, all these observations are earnestly demanded by the science of our day.

A dash at the South Pole is not what I now advocate, nor do I believe that is what British science, at the present time, desires. It demands rather a steady, continuous, laborious, and systematic exploration of the whole southern region with all the appliances of modern investigators.

This exploration should be undertaken by the Royal Navy. Two ships, not exceeding one thousand tons burthen, should, it seems to me, be fitted out for a whole commission, so as to extend over three summers and two winters. Early in the first season a wintering-party of about ten men should be landed somewhere to the south of Cape Horn, probably about Bismarck Strait at Graham's Land. The expedition should then proceed to Victoria Land, where a second similar party should winter, probably in Macmurdo Bay near Mount Erebus. The ships should not be frozen in, but should return to the North, conducting observations of various kinds towards the outer margins of the ice. After the needful rest and refit, the position of the ice and the temperature of the ocean should be observed in the early spring, and later the wintering parties should be communicated with, and, if necessary, reinforced with men and supplies for another winter. During the second winter the deep-sea observations should be continued to the north, and in the third season the wintering parties should be picked up and the expedition return to England. The wintering parties might largely be composed of civilians, and one or two civilians might be attached to each ship; this plan worked admirably during the *Challenger* expedition.

It may be confidently stated that the results of a well-organised expedition would be of capital importance to British science. We are often told how much more foreign governments do for science than our own. It is asserted that we are being outstripped by foreigners in the cultivation of almost all departments of scientific work. But in the practical study of all that concerns the ocean this is certainly not the case; we have to acknowledge no superiors nor equals in this branch of investigation, and if we be a wise and progressive people, British science will always lead the way in this direction. Twenty or thirty years ago we were in profound ignorance as to the condition of all the deeper parts of the great ocean basins; now we have a very accurate knowledge of the conditions which obtain over the three-fourths of the earth's surface covered by the waters of the ocean. This is the most splendid addition to earth-knowledge since the circumnavigation of the world, and is largely due to the work and exertions of the British navy in the *Challenger* and other deep-sea expeditions.

This country has frequently sent forth expeditions, the primary object of which was the acquisition of new knowledge—such were the expeditions of Cook, Ross, and the *Challenger*; and the nation as a whole has always approved such action, and has been proud of the results, although they yielded no immediate return. Shall it be said that there is to be no successor to these great expeditions?

A preliminary responsibility rests on the geographers and representatives of science in this country. It is necessary to show that we have clear ideas as to what is wanted, to show that a good workable scheme can be drawn up. When this has been done it should be presented to the Government with the unanimous voice of all our scientific corporations. Then, I have little doubt, that a Minister will be found sufficiently alive to the spirit of the times, and with sufficient courage to add a few

thousand pounds to the navy vote for three successive years, in order to carry through an undertaking worthy of the maritime position and the scientific reputation of this great empire.

An animated discussion, in which the Duke of Argyll, Lord Charles Beresford, Sir Joseph Hooker, Sir George Nares, Sir Vesey Hamilton, Capt. Wharton, Sir W. Turner, Sir W. Flower, Dr. Buchan, and Mr. W. S. Bruce took part, followed the reading of the paper. All the speakers strongly expressed their conviction that the time had come to make a vigorous attempt to resume the long-interrupted line of advance into the south polar regions by means of a Government expedition.

PHENOMENA OF THE TIME-INFINITESIMAL.[1]

SCIENCE consists in the extension of our knowledge of the external universe, and it brings about this extension in great part by reinforcement of our senses. To bring into the field of observation the very distant and the very small, are therefore regarded as important scientific achievements, and the telescope and the microscope, by means of which this widening of the realm of knowledge has been made, as important implements of research.

Man's relation to time is such that it is difficult to conceive of an instrument which should bring distant events to hand in like manner for inspection. Our time vision turns chiefly in one direction—towards the past—and is obscured by the intervention of something very like a medium or atmosphere, through which we see dimly. As to the future, our thoughts are necessarily confined to matters found by experience of the past to be periodic, or to changes already begun and known by the observation of analogous processes to be likely to run some definite course. In the interpretation of the future by the past, there is much of interest to the physicist; but it is not of this that I would speak to-day. Let us turn our attention rather to the study of minute time intervals in physics—to a consideration of the methods by which we may record what takes place during infinitesimal elements of time. The interest of the physicist in time is confined really to a study of phenomena. He ascribes no property to time itself, beyond defining it after Riemann, as a complexity of the first order.[2]

As between the study of the infinitely great and the infinitesimally small, whether of space or of time, there is a peculiar value to be attached to the latter, because the only methods which have proved the least fruitful in the analysis of the more complex changes which are going on around us, are those which begin with the infinitesimal. We consider an element of mass or of volume, or sometimes merely the element of a surface or line, proceeding then to extend our statements so far as our powers of mathematical expression will permit.

Now the element of time is, of course, purely relative. In certain phenomena the time infinitesimal is so short as compared with any time interval with which we are able to cope experimentally as to be out of reach, just as in special relations the dimensions of the molecule and atom are such that we dare not hope to render these ultimate particles of matter visible even under the microscope. There are periodic phenomena, on the other hand, the periods of which are so great that a lifetime, indeed the entire era covered by history and tradition, affords us a glimpse of but a single time element. Lying between these two there is a great range of phenomena for which the element of time is within our reach. It is by the study of what takes place in such time elements, and the extension of the results thus obtained by analytical processes, that much of our knowledge of physics has been gained. It is to the extension of our powers in the observation of the phenomena of the time interval that we must look in great part for further progress. It has seemed worth while, therefore, to bring together for purposes of comparison some of the methods which have proved fruitful in this respect, and to consider along what line they may be further developed. It is an investigation which will lead us into all departments of science; for phenomena into which the element of time does not enter are unknown.

[1] An address delivered by Prof. E. L. Nichols before Section B (Physics) of the American Association for the Advancement of Science. Madison meeting, August, 1893.

[2] "Eine einfach ausgedehnte Mannigfaltigkeit." (Riemann: Ueber die Hypothesen welche der Geometrie zu grunde liegen. Werke p. 257.)

Since all study of phenomena involves the time element, the consideration of all dynamical problems must begin with the *phenomena* of the *time-infinitesimal*. There are two cases of chief importance:—(1) The study of the time elements of periodic phenomena; (2) the study of beginnings of changes which result from a sudden variation in the condition of equilibrium.

The methods which have been found most useful in the investigation of the phenomena under consideration may be classified as follows:—(1) Visual methods: (*a*) vision by instantaneous exposure, (*b*) vision by periodically interrupted exposure, (*c*) vision by the aid of the revolving mirror. (2) Photographic methods: (*a*) instantaneous exposure of a stationary film, (*b*) photography by the aid of the revolving mirror, (*c*) continuous exposure of a moving plate, (*d*) successive short time exposures of a moving plate. (3) Indirect graphical and electrical methods.

Much of the most important work which has been done in the domain of sound falls within the scope of our present inquiry, and it is in that field that many of the methods just indicated have been developed. The revolving mirror, for example, is a favourite tool of the acoustician; its usefulness is too well known to need mention here, but I wish to remind you that this instrument, chiefly used for the separation of images representing phenomena covering intervals of thousandths of seconds, has been found capable of rendering much briefer events subject to inspection and analysis.

The inventor of the revolving mirror (Wheatstone) found it possible to study time intervals down to within a millionth of a second ("Philosophical Transactions," 1834). He obtained a rate of revolution never since greatly exceeded, I think, of eight hundred revolutions a second. It is evident that he stood at the very threshold of the discovery of the oscillatory discharge, and that it was merely an accident of the relation of resistance and capacity in the circuits which he employed, which prevented him from observing that important form of the electric spark. That he was fully aware of the wide range of investigations to which the revolving mirror is adapted is also clear. He says in the memoir which Faraday presented for him before the Royal Society in 1834: "But this instrument is not confined to observing merely the intermittedness of electric light; whenever a rapid succession of alterations occurs in an object which does not change its place, they may be separately examined by this means. Vibrating bodies afford many instances for investigation; one among these is perhaps worthy to be mentioned. A flame of hydrogen gas burning in the open air presents a continuous circle in the mirror, but while producing a sound within a glass tube regular intermissions of intensity are observed, which present a chain-like appearance, and indicate alternate contractions and dilations of the flame corresponding with the sonorous vibrations of the column of air" (*l.c.* p. 586).

In a later paragraph of the same paper he noted the applicability of the spark in the study of the phenomena of the time-infinitesimal, suggesting a method the importance of which is even now but imperfectly appreciated. "The instantaneousness of the light of electricity of high tension affords the means of observing rapidly-changing phenomena during a single instant of their continued action."

In the hands of Foucault ("Recueil des travaux scientifiques," Paris, 1878), Michelson ("Proc. A.A.A.S.," 1879) also "Papers of Amer. Ephemeris," vols. i. and ii. 1882), and of Newcomb ("Astro. Papers of Amer. Ephemeris," vol. ii.) the revolving mirror has given us our best determinations of the velocity of light; in those of Feddersen ("Beiträge zur Kenntniss des electrischen Funkens, 1857.") Also *Pogg. Ann.* 103, 113, 116 (1859 to 1862), Rood (*Amer. Journal of Science*, vol. ii. 111, p. 160), Trowbridge (*Amer. Journal of Science*, vol. xlii. 111, p. 223), and Boys (*Philosophical Magazine*, vol. xxx. 111, p. 248) and others it has made it possible to resolve the oscillatory spark into its elements.

Feddersen's experiments are especially noteworthy because he succeeded (in 1862) (*Pogg. Ann.* 116, p. 132) in photographing the discharge of the Leyden jar, securing an excellent record of the images seen in the revolving mirror. We are apt at the present day to look back to the introduction of the dry plate as the step necessary to the application of photography to the study of fleeting phenomena, but certainly the results obtained by this early investigator, who used the ordinary wet-plate process of his time, are not inferior in definition or in detail to any which have been published in recent years. Feddersen's researches are indeed worthy of all admiration. He used a concave mirror,

giving excellent images when driven at a speed of one hundred revolutions a second. The velocity was under the regulation to within two per cent., and the millionth of a second represented not merely an appreciable distance upon the negative, it was an *easily measurable* quantity.

More than thirty years ago this German physicist stood, as Wheatstone had done nearly half a century before him, in the very gateway of the domain in which such activity has shown itself of late—the domain of electrical resonance. He was not only the discoverer along experimental lines, of the oscillatory discharge and the demonstrator of the existence of effects which had already been embodied in the analytical work of Helmholtz, Thomson, and Kirchhoff; he anticipated also many of the discoveries of later investigators, and worked out quantitatively the dependence of the rate of oscillation upon capacity, induction, and resistance. Two of Feddersen's photographs have been brought to general notice by reproduction in the fourth volume of Wiedemann's "Electricität." There is another set which I consider even more significant, showing the increase in the number of oscillations with diminishing resistance. It is copied in *fac simile* from the original plate in Fig. 1.

Another forerunner in the development of the methods which it is my privilege to consider, was Prof. E. W. Blake, of Brown University. His results, too, have become classical; but I refer to them because they are related in ways not always

Fig. 1.

recognised in later work. We are all familiar with his interesting photographs obtained by speaking into the mouthpiece of a Bell telephone (Blake, *Am. Journal of Science*, vol. xvi. (3) p. 57), to the diaphragm of which was attached a rocking mirror. Records obtained in a variety of other well-known ways, of some of which I shall have occasion to speak, indicate that these photographs do not give a complete trace of the vibrations which go to make up the articulate utterances by means of which they were excited, but the method is of interest in three particulars:—

(1) It is one of the earliest attempts to substitute photography for vision in the study of the transient phenomena of the sound wave.

(2) It substitutes a moving sensitive plate for the revolving mirror.[1]

(3) It is a distinct forerunner of the method applied some years later with somewhat better success by Froehlich to the analysis of alternate current phenomena.

Throughout the history of the study of the phenomena of the time-infinitesimal we find the tendency to be to supplant visual methods by methods of photographic record. One of the most noteworthy achievements in experimental acoustics, for example, is the application of the manometric flame to the study of sound waves. The drawings made by Kœnig (*Annalen der Physik*, vol. cxxii. p. 666; also in his "Experiences d'Acoustique," pp. 47–84) in illustration and verification of the phenomena of the organ-pipe and of the analysis of complex sounds, have been admired by all of us; and the repetition of his experiments has delighted an entire generation of demonstrators in physics. In how many minds the question of the feasibility of photographing the manometric flame has arisen I do not know, but quite recently it has been shown by Doumer (*Comptes Rendus*, 103 and 105), and independently by Ernest Merritt (Proc. A.A.A.S. 41, p. 82; also *Physical Review*, vol. i.) in a paper read before this section, that by surrounding the sensitive flame with a mantle of free oxygen (after the method of what was once known as the "Budde" light), sufficient actinic intensity may be obtained to ensure an excellent photographic record on a rapidly moving plate. The results of such photographs applied to the analysis of vowel sounds give evidence of the extraordinary fidelity of the sketches published by Kœnig. They also afford a basis for the study of timbre of the sounds to which they correspond, which is open to one objection only, viz. to the uncertainty as to the influence of the inertia of the diaphragm upon the character of the image. Of this source of error I shall have more to say in connection with some other researches.

Other interesting examples of the study of the time-element might be drawn from this field; indeed, the science of sound is of necessity largely made up of such work. The beautiful photographs of vibrating strings by Menzel and Raps (*Annalen der Physik, N.F.* 44, 1891, p. 623), which are so fitting an appendix to the earlier labours of Helmholtz (*Die Tonempfindungen*, p. 137), may serve to illustrate the usefulness of the method of photography on a moving plate.

In the study of periodic phenomena two distinct methods of investigation have been established. The first of these consists in the isolation of a desired element of the cycle at each repetition for as long a time as may be necessary to obtain a satisfactory record of the existing conditions. By the selection successively of many neighbouring elements, we get in this way at last the data from which to construct a complete diagram of the cycle.

This principle has been most fruitful in enabling us to analyse periodic processes not easily approachable by more direct means. The most notable application has been that which is commonly spoken of as the "method of instantaneous contact," well known to the student of alternating current phenomena.

It is to Joubert[1] (1880) that we owe this ingenious adaptation of the device of properly timed repetitions of instantaneous observations of periodic phenomena (a principle which underlies the phenakistoscope and similar well-known instruments). He made use of it in the study of the changes of potential in the circuit of the alternating current dynamo, and between the terminals of the Jablochkoff candle.

In the same year the method was discovered independently, and applied to the study of the Brush arc-lighting dynamo by B. F. Thomas.[2] Joubert pointed out the method of using the quadrant electrometer in alternating circuits, also that the galvanometer might be utilised. ("On peut mesurer cette intensité par l'electromètre mais on peut aussi employer le galvanomètre puisque les contacts successive correspondent toujours a une même phase du courant.") He discovered the retardation of phase in the current curves of the alternating dynamo, and the peculiar distortion of the curves in the circuit containing an arc lamp, a matter more fully investigated at a later day by Tobey and Walbridge.[3] Thomas during this first period in the history of the Joubert method used a ballistic galvanometer and condenser.

The periodic phenomena of the alternating current circuit have been among the most important to which the study of the time-element has been applied, and it is to the method of instantaneous contacts that we owe much of the progress of the last thirteen years. It is interesting to note the extension of

1 Stein, in a paper cited by Prof. Blake, *Pogg. Ann.* 159 (1876), describes a similar device, but it is difficult to ascertain from his paper to what extent he succeeded with his experiments.

1 "Sur les Courants alternatifs et la force electromotive de l'arc electrique." *Comptes Rendus*, vol. xci. p. 161, July 19, 1880.

2 "Observations on the electromotive forces of the Brush dynamo-electric machine." (title only.) Proceedings A.A.A.S. vol. xxix. p. 277 (1880). Prof. Thomas gave the results obtained, and described the method eleven years later in a communication to the Institute of Electrical Engineers, entitled "Notes on Wiping Contact Methods for Current and Potential Measurements," Translations of the American Institute of Electrical Engineers, vol. ix. p. 263.

3 "Investigations of the Stanley Alternate Current Arc Dynamo." Trans Am. Inst. Electrical Engineers, vol. vii. p. 367.

this method in the study of a variety of allied phenomena. After the publication of Joubert's papers the method seems to have come into common use in the physical laboratories, particularly in the exploration of the fields of continuous current dynamos and motors.

In 1888 it was applied by Duncan, Hutchinson, and Wilkes ("Experiments on Induction Coils," *Electrical World*, vol. ii. p. 160, 1888) to the study of induction coils and transformers. To them we owe the first set of complete diagrams relating to the performance of this class of alternating current apparatus. In the same year Meylan ("Sur les Appels Magnetiques," *La Lumière Electrique*, xxvii. p. 220, 1888) used an interesting modification of the method in the investigation of the vibratory magnetic call-bell of Abdank.

In the same year appeared the first definite data with reference to the Westinghouse alternating dynamo, at the hands of Messrs. Searing and Hoffmann ("Variation of the Electromotive Force in the Armature of a Westinghouse Dynamo," *Journal of the Franklin Institute*, vol. cxxiii. p. 93), of Stevens Institute. Then followed in the order named the researches of Ryan and Merritt ("Transformers," Trans. Am. Inst. Electrical Engineers, vol. vii. p. 1, 1889), Humphrey and Powell ("Efficiency of the Transformer," *Ibid*, vol. vii. p. 311), Tobey and Walbridge (*Ibid*, vol. vii. p. 367), of Marks (*Ibid*, vol. vii. p. 324), of Herschel (*Ibid*, vol. vii. p. 328), of Fortenbaugh and Sawyer (*Ibid*, vol. vii. p. 334).

In all these investigations the methods under consideration have been used with varying accessories in the problem of the transformer.

In 1890 it was applied under much more difficult conditions to the analysis of the "ball and point effect" by Archbold and Teeple (see Nichols, "On Alternating Electric Arc between a Ball and Point," *American Journal of Science*, vol. xli. p. 1).

In 1891, Thompson ("Study of an Open Coil Arc Dynamo," Trans. Am. Inst. Electrical Engineers, vol. viii. p. 375) determined the intricate changes of induction in open coil arc lighting machines by means of the same method, and Ryan ("Relation of the Air Gap and the Shape of the Poles to the Performance of Dynamo-electric Machinery," *Ibid*, p. 451) utilised it in his investigations of the influence of the air gap upon the performance of dynamos and motors. In 1892, Duncan ("Note on some Experiments with Alternating Currents," *Ibid*, vol. ix. p. 179) described modifications of the method of instantaneous contacts by means of which the rapidity of reading is greatly enhanced.

During the present meeting, you will doubtless have the pleasure of listening to a description of the applications of the same device to the study of electrostatic hysteresis. (Reference is here made to the paper presented by Messrs. Bedell, Ballantyne, and Williamson: "Alternate Current Condensers and Dielectric Hysteresis," *Physical Review*, vol. i. p. 91. Subsequent note.)

Such has been, in brief, the history of a method by means of which in greater degree than of any other we have been able to extend and complete our knowledge of alternating current phenomena.

To the practical electrician and to the theorist alike, the domain has been one of the most attractive of those which have been developed in recent years. To the electrical engineers of the younger generation the very complexity of alternate current theory has proved a benefit. It has forced them to increased mathematical proficiency and to more rigorous thinking; it has, indeed, served as an excellent source of discipline. What the problems of submarine telegraphy did for the English electricians who served their apprenticeship during the early days of the cable-laying industry, compelling the development of those sturdy qualities which have been so highly serviceable in every branch of electrical progress since, the intricacy of alternate current practice is unquestionably doing for the younger school which is growing up to-day in this country. The difficulties which have to be met and overcome in this field of work will have an excellent influence upon the manner in which the problems of the future will be approached.

Another investigation, which owes its existence to a most ingenious application of this same principle of instantaneous contacts periodically repeated, is well known to all of you. I refer to Prof. E. H. Hall's[1] study of periodic heat-flow in the cylinder walls of the steam-engine by means of thermo-elements embedded within the metal and connected momentarily during a selected time-element in the course of each stroke with a sensitive galvanometer. To my mind no more interesting example of the indirect method of studying the phenomena of the time element could be found than this suggestive memoir.

[1] "A Thermo-Electric Method of Studying Cylinder Condensation in Steam-Engine Cylinders." Trans. Am. Inst. Electrical Engineers, vol. viii. p. 236.

The method of instantaneous contacts has been a fruitful one, and productive of high results, but it does not yield a knowledge of any individual time-element, nor the picture of any single completed cycle. Numerous attempts to record single cycles have been made, the results of which are of considerable interest, because they deal with the more direct study of the time-infinitesimal.

The device which lay nearest to hand, and which by its performance seemed to promise success in this direction, was the magneto-telephone. The investigations of Mercadier (*Journal de Physique*, vol. ix. pp. 217 and 282) had already paved the way to some extent, when Froehlich described his experiments upon the optical representation of the movement of the diaphragm of the telephone, followed almost at once by Thomson.

Froehlich[1] reported his preliminary results to the Electrotechnische Verein of Berlin, in 1887. Elihu Thomson ("An Indicator for Alternating Circuits," *La Lumière Electrique*, vol. xxvii. p. 339 (1888) brought out his indicator for alternating circuits, an instrument in which the movement of a diagram was amplified by levers, and then made visible by optical means (or photographed) in the same year. Froehlich's method in its complete form, including the photography of the images from the involving mirror,[2] was first described in the year 1889. Some of the curves published in the papers just cited, and particularly the experiments shown in the exhibition of the method at the Frankfort Electrical Exposition of 1891, are most striking, but considering the method by which they are produced, the question inevitably arises as to the part played by the inertia of the moving masses.

Froehlich himself points out the necessity of great care in the matter of the adjustments, and of distinguishing the natural oscillation of the plate, which are frequently superimposed upon those to be recorded. Some experience with Froehlich's method has convinced me that not only is extraordinary skill necessary in order to obtain, by means of a mirror attached to the diaphragm of a telephone, curves which should represent, even with a fair approximation, the law of whatever periodic changes we may desire to record, but that the attainment of the proper adjustment is a matter so entirely fortuitous, and its maintenance so uncertain, as to deprive the method of much of its usefulness. One may indeed hope to get, by means of successive adjustments, curves which correspond to a known type, but whether in passing to new and unknown types the apparatus retains its faithfulness, is always a question.

By way of illustration, I introduced three of an extended series of curves obtained by this method with a telephone in circuit with an alternating current dynamo. The character of the cycle had been determined by the method of instantaneous contacts. The true cycle was represented by a curve of sines, but with the apparatus under consideration complex curves of the kinds shown in figures 2 and 3 were the rule; curves even approximating to simple sinuosity were the rare exception.

The difficulties of the method lay not merely in the tediousness of adjustment, but rather in the tendency to revert to complex forms under changes of condition so slight as to be entirely beyond control. The remedy clearly consists in the elimination of mechanism and the reduction of inertia of the moving parts. Following the suggestion of an assistant, Mr. E. F. Northrup, I tried the following experiments:—

A mercury stream flowing from the contracted nozzle of a funnel (Fig. 4) was made to pass between two metal terminals which were attached to the poles of a large Holtz machine. A portion of the falling column of mercury within the electrostratic field was illuminated by means of an arc lamp, and so much of it as could be seen through a horizontal slit was photographed by transmitted light. The sensitive plate was given rapid vertical motion through the field of the camera. When the machine was out of action there resulted a vertical trace running the length of the developed plate. As soon as the machine was put

[1] "The Optical Representation of the Movements of a Telephone Diaphragm." *La Lumière Electrique*, vol. xxv. p. 180 (1887).
[2] Froehlich: "Ueber eine neue Methode zur Darstellung von Schwingungskurven." *Electrotechnische Zeitschrift*, bd. x. pp. 345, 369 (1889).

into operation, deflection of the mercury stream occurred. It was the object of the experiment to determine the performance of the stream under the sudden fluctuations of the field which occurred when the Holtz machine was under rapid discharge.

Fig. 5 is from a photograph taken when nearly one hundred sparks a second were passing between the poles.

Other photographs were obtained in a similar manner, the deflecting forces, however, being due to the action between the

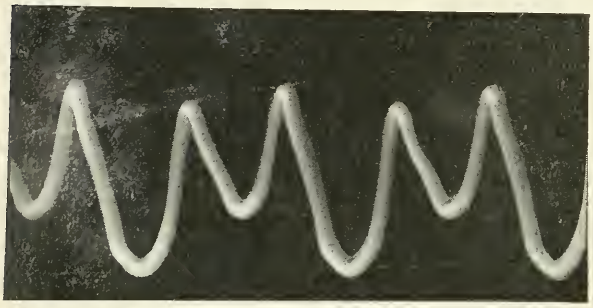

FIG. 2.

lines of a stationary magnetic field and those of an alternating current traversing the mercury column. The arrangement of the apparatus is shown in Fig. 6. The mercury stream was introduced into the circuit of the alternating current dynamo, already made use of in the experiments upon Froehlich's method. It flowed through a strong magnetic field with horizontal lines. The transverse oscillations of the mercury under these con-

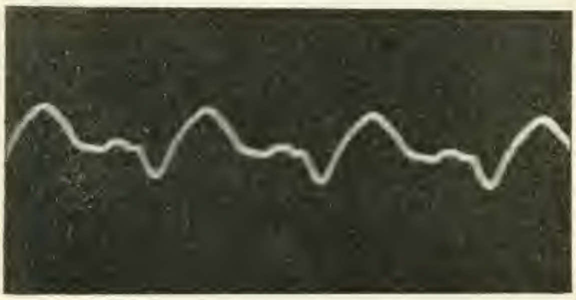

FIG. 3.

ditions were very apparent. When photographed by means of a camera with optical axis parallel to the lines of force, the stream strongly illuminated from behind and viewed through a narrow horizontal slit, as in the previous experiment, a sinusoidal trace was obtained. All the complexities of the telephonic trace disappeared in these records, and curves corresponding to those of the method of instantaneous contact were always pro-

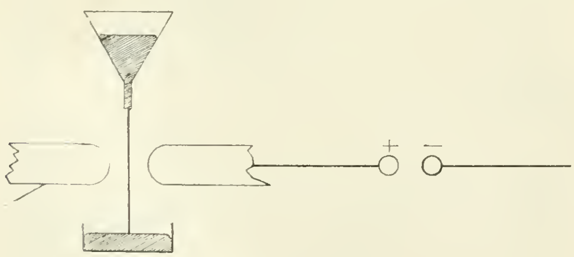

FIG. 4.

duced. The experiment was made by Mr. Henry Floy, to whose efforts the photographs by Froehlich's method are also due. This method has not been further developed. I introduce it here to show that increased accuracy of record may be looked for as the result of reducing in any practicable manner the mass of the indicating device.

Another attempt to record single periods in dynamo-electric work should be mentioned here. It is described by Moler[1] in a recent paper. By means of a D'Arsonval galvanometer with a period of vibration of a few thousandths of a second, curves of varying potential are traced, which show excellent agreement with measurements by the method of instantaneous

FIG. 5.

contacts. The instrument is not free from the errors due to inertia. It is reliable only in recording changes of period considerably greater than its own, but its use is a step in a direction along which progress may be looked for.

Thus far I have dealt with methods of studying periodic changes, the time-elements of which are easily within reach

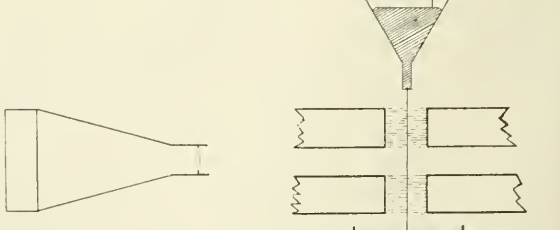

FIG. 6.

through experimental devices. I might have devoted myself with as good reason to the consideration of recent advances in the study of electrical oscillations of a higher order of frequency. This is a department of physics in which much has been done of

[1] "A Dynamo-Indicator, or Instantaneous Curve-writing Voltmeter." (Trans. Am. Elec. Engineers, vol. ix., p. 223.)

late, but so much has been written at second-hand, as well as in the way of original treatment, that further reiteration is uncalled for. The work of Hertz and of his host of followers is familiar to us all. In the study of electrical oscillations even of very high frequency, photography has been used with success, and details of the phenomena of time-elements truly infinitesimal have been secured. By the labours of Wiener[1] waves of a still higher order than those which have occupied the attention of the electrician have been photographed, and a new field of the greatest promise has been thrown open to the optician. The isolation of a single light vibration may indeed still be as far from us as is the inspection of the molecule by means of the microscope, but in the meantime we have in the photography of a system of standing light-waves, an achievement well worth celebrating.

In the investigation of the phenomena of the time-infinitesimal, so far as periodic changes are concerned, we see that the experimenters of the present time are gaining much of detailed knowledge. There is another field equally important, in my opinion, which is as yet for the most part unexplored. The study of the beginnings of changes brought about by abrupt shifting of the conditions of equilibrium is one from which very much may be expected. Already suggestive beginnings have been made, but the researches have not been pushed to the limit of the experimentally possible. Oftentimes interesting observations of what might be termed "startling phenomena" have been recorded, but quantitative results are lacking. Take for example the brilliant work of Becquerel (*Comptes rendus*, 96, pp. 121, 1215, 1853) with the phosphorescope. What a mass of fascinating and suggestive material that savant has gathered into the first volume of his book on light! (*La Lumière*, i. pp. 206–422.) What a world of interesting material these preliminary observations present to him who shall undertake to determine quantitatively, wave-length by wave-length, the changes which the radiations from the numerous luminescent materials undergo, beginning with the instant of exposure and following the vanishing light until it is gone.

Of a few isolated cases which have been forced upon us by their practical importance we have some complete knowledge already. With the phenomena in cables when current is suddenly introduced or circuit is broken, we are reasonably familiar. The case of the charge and discharge of condensers has been treated analytically under assumptions the precise truth of which is still to be verified. The detailed study by experiments carried to the utmost refinement, of the very cases which seem to have been most completely covered by theory, is especially important; since in this way only can the assumptions upon which our analysis is based be rigorously determined, and the necessity of modifications be ascertained. For some of this work methods already in use in the study of periodic phenomena will suffice. The curve-writing voltmeter, for example, may be made to give records running to within a thousandth of a second of the instant when a process such as electrolysis, electrolytic polarisation, voltaic action, or the charge and discharge of a condenser begins. Instruments such as the von Helmholtz pendulum, for the isolation of definite small time intervals, may also be applied to a great variety of progressive phenomena, enabling us to approach by successive steps almost to the very beginnings of the changes to be analysed. Concerning known methods let me point out, in conclusion, that photography with the moving plate is a means, the limitations of which have not yet been discovered. It is equally applicable to periodic and to progressive phenomena, often with results of unexpected beauty and significance.[2]

The remarkable experiments of Mach (*Wiener Sitzungsberichte*, 95, p. 764, also 97, p. 41) and of Boys ("On Electric Spark Photographs," &c., NATURE, vol. xlvii. p. 415) indicate that the dry plate is still abundantly exposed within intervals so short that the swiftest of modern projectiles give images as of a body at rest.

The laws of electrical resonance have already been so far determined that we can construct condensers, the duration of the discharge of which is a matter of computation, and the precise moment of the discharge of which after a given event is quite within control. This single device, consisting of the exposure of the photographic plate by means of a properly timed spark, brings under observation a set of time intervals of a new and higher order of brevity. Much is destined to be learned by means of it concerning the nature of matter, and much more, I think, from other, possibly still more powerful, methods which will doubtless be developed when the importance of the study of the time-infinitesimal is more generally recognised.

[1] "Stehende Lichtwellen und Schwingungsrichtung des polarisirten Lichtes." *Annalen der Physik N.F.* vol. xl. p. 203.

[2] In photographing the alternate current arc a single exposure of a continuous current lamp upon the moving plate, by way of check, brought out the seat and precise nature of the hissing of the arc in a manner scarcely to be reached in any other way. For the method used, see "A Photographic Study of the Electric Arc," Trans. Am. Inst. Electrical Engineers, vol. viii. p. 214, 1891.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—At a meeting of the Ashmolean Society, held at the Museum on Monday, 27th inst., Prof. Odling was elected President for the ensuing year, and Messrs. F. J. Smith and G. C. Bourne were re-elected Secretaries. Mr. E. J. Stone read a paper on the rainfall at Oxford during the last seventy-eight years, and Prof. E. Ray Lankester read a paper on fresh-water jelly-fishes.

At the meeting of the Junior Scientific Club, on Friday, 24th inst., papers were read by Dr. Ritchie, on anthrax spores and bacilli; by Mr. G. B. Cronshaw, on explosions in coal-mines; and by Mr. A. L. Still, on plants and their standing army.

CAMBRIDGE.—The Special Board for Physics and Chemistry report that the Cavendish Laboratory, founded and equipped by the munificence of the late Duke of Devonshire, has become incapable of accommodating the large number of students desiring tuition in Physics. In the present term no less than 135 students are at work in a disused galvanised iron dissecting-room, which, on its vacation by the Professor of Anatomy, has been placed at the disposal of the Professor of Physics as a temporary laboratory. Its site will, however, soon be required for the Sedgwick Memorial Museum of Geology, and the Board feel that the time has come for the permanent extension of the Cavendish Laboratory. An adjoining site is available between it and the Engineering Laboratory; but the problem of funds for building and equipment is less easy to solve, unless a benefactor as generous as the late Chancellor should make his appearance. The high position deservedly held by the Cavendish Laboratory, entrusted as it is with much work of national importance, makes it reasonable to hope that Prof. J. J. Thomson will be able to obtain the means for the desired extension.

Mr. W. Gardiner and Mr. A. C. Seward have been re-appointed University Lecturers in Botany, and Dr. Hill, Master of Downing College, Lecturer in Advanced Human Anatomy, for five years. Dr. Hill has also been appointed Chairman of the Examiners for the Natural Sciences Tripos.

The Local Examinations Syndicate report that the work done in the scientific branches of the Higher Local Examinations during the past year was on the whole satisfactory. Imperfect experimental work in chemistry, and lack of practical instruction in zoology, are among the weaker points revealed.

The Examinations in Sanitary Science seem to be increasingly appreciated by medical men. During the present year eighty-seven candidates have presented themselves, and of these fifty-eight received diplomas in Public Health.

THE *Times* correspondent at Paris says that an International University alliance is in course of formation there. Its object is to facilitate the passing of students from one University to another, to promote travelling scholarships and the exchange of information, to multiply periodical celebrations, and to "draw the attention of the Universities to the question of introducing greater justice into international relations."

SCIENTIFIC SERIALS.

Wiedmann's Annalen der Physik und Chemie, No 11.—On the speed of electrolytic ions, by F. Kohlrausch. This is a compilation of tables of absolute velocities, of mobilities, and of coefficients of electrolytic friction according to the latest and most reliable data.—Contributions to the knowledge of the absorption and branching of electric oscillations in wires, by Ignaz Klemencic.—The resistance which causes evolution of heat during the passage of very rapid oscillations depends upon the magnetic permeability of the wire, but in a different

manner from that in the case of a constant current. The amounts of heat developed in wires of iron, German silver, brass, and copper 6 cm. long and of 0·018 cm. radius, were in the proportion of 10·5 : 1·75 : 1 : 1, the last being probably a little too large. The branching of the oscillations is only affected by the self-induction of the wires, not by their resistance.—The emission of hot gases, by F. Paschen (see p. 82).—A simple method of testing the conductivity of dielectric liquids, by K. R. Koch. The apparatus used for this method is a modified Dewar capillary electrometer, in which a drop of the substance to be examined takes the place of the drop of sulphuric acid usually employed for determining differences of potential. Any electrolytic polarisation is indicated by a movement of the drop of liquid, which should not be more than 0·5 mm. long. The conductivity of various dielectrics has thus been studied, and has in many cases been found to be due to impurities. Benzol, carefully cleaned and freed from moisture, ceased to show any polarisation.—On the magnetic susceptibility of oxygen, by R. Hennig (see Notes).

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, November 2.—Dr. Armstrong, President, in the chair.—The following papers were read:—The action of bromine on azobenzene: a correction, by H. E. Armstrong. The colourless bromination product of azobenzene is tetrabromobenzidine, and not a tetrabromazobenzene, as stated by Werigo.—The origin of colour. X. Coloured hydrocarbons, by H. E. Armstrong.—The formation of the hydrocarbon "truxene" from phenylpropionic acid and from hydrindone, by F. S. Kipping. On heating hydrindone with dehydrating agents, a hydrocarbon of the constitution

$$\begin{array}{c} C_6H_4 . \dot{C} : C . CH_2 \\ \dot{C}H_2 . \dot{C} : \dot{C} . \dot{C}_6H_4 \end{array}$$

is formed; it is identical with truxene, to which the molecular formula $C_{27}H_{18}$ has been erroneously assigned by Liebermann and Bergami. Further, Gabriel and Michael's "tribenzoylenebenzene" in all probability has the molecular formula $C_{18}H_8O_2$ instead of $C_{27}H_{12}O_3$, as has previously been supposed.—The action of aluminium chloride on heptylic chloride, by F. S. Kipping. A crystalline ketone of the composition $C_{14}H_{20}O$, is formed by the interaction of heptylic chloride and aluminium chloride.—The inertness of quicklime. II. The interaction of chlorine and lime, by V. H. Veley. Dry chlorine has no appreciable action on quicklime below 300°; above this temperature, a partial replacement of oxygen by chlorine occurs.—Note on hyponitrites, by D. H. Jackson. No hyponitrite is formed during the reduction of sodium nitrate with aluminium or barium amalgam. Diver's process for preparing hyponitrites gives the best results when a weak sodium amalgam is employed, and when the action proceeds at a low temperature.—The interaction of hydrogen chloride and potassium chlorate, by W. H. Pendlebury and Mrs. McKillop. The authors have determined the amounts of oxidising gases removed, during successive periods of time, from an aqueous solution of hydrogen chloride and potassium chlorate by a current of air. The action of sunlight on the solution materially increases the quantity of oxidising gas carried away by the air current.—The formation of indoxazen derivatives, by W. A. Bone. The author has studied the action of alkalis on orthochloronitrobenzaldoxime with the object of preparing nitrindoxazen; in place of this substance, however, the isomeric 1 : 2 : 5 nitrosalicylonitril was isolated, molecular change having occurred during the interaction. A number of new nitro-derivatives were obtained.—The interaction of benzylamine and phenacyl bromide. Synthesis of piazine derivatives, by A. T. Mason and G. Winder. Phenacyl bromide and benzylamine readily interact with formation of the hydrobromides of monophenacylbenzylamine, Ph . CO . CH_2 . NH . CH_2Ph and diphenacylbenzylamine (Ph . Co . $CH_2)_2$N . CH_2 . Ph; on liberating the bases, molecular changes occur. In the case of the monophenacyl-derivative, 1 . 4-dibenzyl-2 : 5-diphenylpiazine dihydride is obtained; when this substance is heated to the boiling-point, it yields toluene and 2 : 5-diphenylpiazine.

$$\begin{array}{c} CH{\cdot}N{\cdot}CPh \\ \ddot{C}Ph{\cdot}\ddot{N}{\cdot}\ddot{C}H \end{array}$$

A number of other piazine derivatives are also described.—The interaction of quinones and metanitraniline and nitroparatoluidine: a preliminary note, by J. Leicester. The author describes a number of condensation products of quinones with *m*-nitraniline and nitro-*p*-toluidine.—Preparation of α-β-diphenylindoles from benzoïn and primary benzenoid amines, by F. R. Japp and T. S. Murray. A mixture of benzoïn, aniline, and zinc chloride yields α-β-diphenylindole, in accordance with the following equation

$$Ph . NH_2 + Ph . CO . CH(OH)Ph = C_6H_4\left\langle\begin{array}{c} C \\ NH \end{array}\right\rangle CPh_2 + 2H_2O.$$

New substituted indoles may be prepared by the employment of other aromatic amines in place of aniline.

Mathematical Society, November 9.—A. B. Kempe, F.R.S., President, in the chair.—The resolution for the incorporation of the Society, and the list of names as new Council for the session 1893–4 (see NATURE, vol. xlviii. p. 619), were carried unanimously.—The President gave a brief account of the life and work of the late W. S. B. Woolhouse, and then accompanied the presentation of the De Morgan medal, which had been awarded by the Council in June last to Prof. F. Klein, of Göttingen, with an outline sketch of the grounds of the award. Prof. Greenhill, F.R.S., and Dr. Forsyth, F.R.S., who had been deputed by Prof. Klein, in his unavoidable absence, to receive the medal, suitably acknowledged the gift. The following communications were made:—A mechanical solution of the problem of tethering a horse to the circumference of a circular field, so as to graze over an n^{th} part of it, by Prof. L. J. Rogers. (The solution turned on a property of the cycloid).—The stability of certain vortex motions, by A. E. H. Love. The paper contains investigations of the steady motion and small oscillations of Kirchhoff's elliptic vortex, which rotates uniformly in the midst of an infinite mass of liquid, and of Hill's elliptic vortex, which rotates uniformly in the midst of a mass of liquid filling a confocal rigid envelope, the envelope rotating with the same angular velocity. It is proved that Kirchhoff's vortex is stable for all modes of oscillation in which the boundary ceases to be elliptic, provided the major axis is less than three times the minor axis. It is also proved that if the boundary is any ellipse, the vortex rotates steadily with angular velocity suitable to its eccentricity, and that it is impossible for it to change form and remain elliptic. The characteristics of the various modes of oscillation are made out, viz. it is shown that for each mode there is a definite number of wave-lengths of a simple harmonic disturbance in the circumference, provided the amplitude of the disturbance is measured by the ratio of the normal displacement of a point in the boundary to the central perpendicular on the tangent at the point. The general period equations are obtained, and it is shown in particular that Hill's vortex is always stable for elliptic displacements of the boundary of the vortex, the frequency for such displacements tending to zero when the vortex degenerates into a Kirchhoff's vortex by indefinite expansion of the external boundary of the liquid, thus verifying the results found in the more special case. It is also verified that the vortex sheet, which is another degenerate Hill's vortex, is always unstable for the more complex types of disturbance. Messrs. Hill, Basset, Greenhill, and Bryan spoke upon the paper.—Cyclotomic quartics, by Prof. G. B. Mathews.—On the application of elliptic functions to the curve of intersection of two quadrics, by J. E. Campbell.—Note on the theory of groups of finite order, by Prof. W. Burnside, F.R.S. The only quite general theorem at present known concerning the structure of a group (of finite order) is the following, due to Herr Sylow: "If p^a is the highest power of a prime p that divides the order of a group, the group contains a single conjugate set of sub-groups of order p^a, and the number of such sub-groups is congruent to unity, modulus p." In the theory of groups of finite order, and especially in considering the possible structure of a group of given order, this theorem is fundamental. From its enunciation it is clearly independent of the form in which the group may be represented. The only published proofs of it, to the best of the author's knowledge, are the original proof by Herr Sylow (*Math. Ann.* vol. v.), and a proof given by Herr Netto in his "Substitutionentheorie." These both depend essentially on the representation of the group as a group of substitutions, and also on the conception of transitivity in connection with this form of representation. A proof of the theorem is given in the first of these notes, which is as fundamental in conception as

the theorem itself, being entirely independent of the form in which the group may be supposed to be expressed. The latter part of the paper dealt with the orders of simple groups in certain cases.—Prof. Hudson showed and explained some mechanical constructions (by his son, R. W. Hudson) for the parabola, hyperbola, cubical parabola, and semi-cubical parabola.

Royal Meteorological Society, November 15.—Dr. C. Theodore Williams, President, in the chair.—Mr. F. J. Brodie read a paper on the great drought of 1893, and its attendant meteorological phenomena. The author confined his investigation to the weather of the four months, March to June, during which period the absence of rain was phenomenal; barometric pressure was greatly in excess of the average, temperature was high, with a large diurnal range, and the duration of sunshine was in many places the longest on record. The mean temperature over England was about 4° above the average. Along the south and south-west coasts the sunshine was between 50 and 60 per cent. of the possible duration. The rainfall was less than half the average amount over the southern and eastern parts of England, the extreme south of Ireland, and a portion of Durham and Northumberland; while over the southern counties of England generally the fall amounted to less than one-third of the average. The smallest number of days with rain was at the North Foreland, where there were only eighteen.—Mr. W. Marriott gave an account of the thunder and hailstorms which occurred over England and the south of Scotland on July 8, 1893. Thunderstorms were very numerous on that day, and in many instances were accompanied by terrific hailstorms and squalls of wind. It was during one of these squalls that a pleasure-boat was capsized off Skegness, twenty-nine persons being drowned. About noon a thunderstorm, accompanied by heavy hail and a violent squall of wind, passed over Dumfries and along the valley of the Nith; many of the hailstones measured from 1 inch to $1\frac{1}{2}$ inches in length. At the same hour a similar storm occurred at Peterborough. From about two until ten p.m. there was a succession of thunderstorms over the north-east of England and south-east of Scotland, and at many places it was reported that the thunderstorms were continuous for nine hours. Two storms were remarkable for the immense hailstones which fell during their prevalence over Harrogate and Richmond in Yorkshire. The hailstones were 4 and 5 inches in circumference, and some as much as 3 inches in diameter. Great damage was done by these storms, all windows and glass facing the direction from which the storm came being broken. It is computed that within a radius of five miles of Harrogate not less than 100,000 panes of glass were broken, the extent of the damage being estimated at about £3000. The thunderstorms in the northern part of the country travelled generally in a north-north-westerly direction at the rate of about twenty miles an hour. They appear to have taken the path of least resistance, and consequently passed over low ground and along river valleys and the sea coast. Several storms seem to have followed each other along the same track.

Royal Microscopical Society, November 15,—A. D. Michael, President, in the chair.—Mr. C. L. Curties exhibited and described a microscope by Leitz, of Wetzlar, made on the English model, with tripod foot and inclining body, horse-shoe stage, and sub-stage fittings.—Mr. A. W. Bennett gave a *résumé* of Mr. W. West's paper on new British fresh-water Algæ.—Prof. F. Jeffrey Bell read a paper by Mr. G. Sandeman, on a parasitic disease in flounders. The author stated that there are often found on the coast flounders having small round swellings under the skin, which have been described under the name of multiple tumours. The tumours have the appearance of eggs, deposited irregularly beneath the skin. They cause a slight projection of the skin, which sinks slightly between the individual ova, but, when very many are present in one mass, the large tumour which is formed projects considerably from the body, and is sometimes even a pedunculated or finger-shaped formation. On microscopic examination, the contents of the tumours present all the characteristics of eggs. The cause and habits of the parasite are so obscure that the author finds it impossible to pronounce a definite opinion on the subject.—The President announced that the Society's conversazione would take place in the early spring.—Mr. C. Beck raised a discussion as to the possibility of obtaining a standard tube-length. Dr. W. H. Dallinger congratulated Mr. Beck upon the able way in which he had brought the matter before them. He thought that a committee should be appointed to discuss the whole question.

Paris.

Academy of Sciences, November 20.—On a new model of a reverberatory electric furnace with movable electrodes, by M. Henri Moissan.—On equations of mixed functions and a problem of geodesics, by M. G. Kœnigs.—On differential equations of the second order with fixed critical points, by M. Paul Painlevé.—On the means of increasing the security of high tension alternate-current distribution, by M. G. Claude. The elimination or diminution of the capacity of the mains with regard to the earth would make it necessary to touch the two poles of the circuit to receive a shock capable of endangering life. This may be obviated most conveniently by neutralising the capacity by self-inductions placed along the circuit.—Action of some metals upon acid solutions of their chlorides, by MM. A. Ditte and R. Metzner. If a plate of tin is plunged into a concentrated hydrochloric acid solution of stannous chloride upon which a layer of water has been poured, crystals of tin are rapidly formed near the surface of separation. The arrangement amounts to a galvanic cell, in which the same electrode is plunged into different liquids. A solution of stannic chloride shows the same phenomenon, which takes place as soon as the water has, by the diffusion of the salt, become sufficiently conducting to permit the passage of the current. The tin above the surface of separation merely acts as a negative electrode, and may be replaced by a platinum wire. That the phenomenon is one of electrolysis may be shown by replacing a small portion of the bar of tin by an insulator placed at the surface of separation. No crystals are deposited until the two separated portions are brought into communication by the diffusing salt. When the stannic chloride solution is placed in a porous pot in a vessel of acidulated water, and the two liquids are joined by platinum plates, no electrolysis takes place; but cadmium treated by the first method shows precisely similar phenomena. Zinc, which is easily dissolved by the most dilute hydrochloric acid, shows nothing similar. Nickel, which is quickly covered with a protecting layer of hydrogen, and also bismuth and antimony, which are insoluble in hydrochloric acid, show no phenomena analogous to those exhibited by tin.—Means of preserving wood from being worm-eaten, by M. Émile Mer. The attacks on the sap-wood by the insects are due to the presence of starch in this tissue. It may therefore be inferred that the fact of the hard wood being free from the invasion is due to its not being amyliferous. The alburnum may be protected by ridding it on starch. This may be done by annulation of the bark at the upper end of the trunk, and by suppressing all buds developed there. Spring is the best season for this operation. The starch has disappeared by autumn, and the trees may be felled during October. Carpenters and joiners will, in this way, be enabled to utilise the whole or part of the sap-wood.—On the development and maturation of the cider apple, by M. L. Lindet. In the maturation of the cooked apple the same transformations take place as during the ripening of the fruit on the tree. The quantity of starch accumulated in the green fruit diminishes, and this diminution coincides with the increase of the saccharose and inverted sugar; these sugars disappear in their turn through respiration.—On the minute structure of the terminal plates of the motor nerves of striated muscle, by M. Charles Rouget.—On the nematodes of the pharyngean glands of ants, by M. Charles Janet. The two glands taken from an ant from an artificial nest (*Formica rufa*) appeared in the form of bunches of yellow tubes resembling actinia with numerous tentacles. Each tube was occupied by one or more *Rhabditis*, which could be dislodged in great numbers by slight pressure on the cover-glass. The whole nest turned out to be thus infested, although the ants appeared to be in good health. The nematodes appear to be a larval form of the sexed individuals living in a free state in the detritus of the nest.—On the polymorphism of *Peridinium acuminatum* Ehr, by M. Georges Pouchet.—On the north-east extremity of the main body of Mont Blanc, by MM. L. Duparc and L. Mrazec.—On the origin of the Alps of Chablais and Stockhorn, in Savoy and Switzerland, by M. Hans Schardt.—Discovery of another pre-historic magdalenoan deposit in the Vézère valley, by MM. Paul Girod and Élie Massénat.—On the variation of composition of lake-water with the depth, by M. A. Delebecque.

New South Wales.

Linnean Society, September 27.—The President, Prof. David, in the chair.—The following papers were read:—Descriptions of new species of *Bostrychidæ*, by Arthur M. Lea.

—Botanical notes from the Technological Museum, Sydney. No. 1, by J. H. Maiden and R. T. Baker. The paper embodied a number of fresh localities for New South Wales plants, and also New South Wales localities for plants hitherto known only from Queensland, viz. *Decaspermum paniculatum*, *Psychotria nematopoda*, *Tetranthera ferruginea*, (*Litsæa hexanthus*). There are also recorded observations on *Amperea spartioides* with pedicellate female flowers, several at each node, *Hovea acutifolia*, with glabrous pods; notes on *Melodorum Leichhardti*, *Sideroxylon myrsinoides*, *Blechnum serrulatum*, *B. cartilagineum*, *Eucalyptus saligna*, and others.—Preliminary note on a species of *Balanoglossus* from the coast of New South Wales, by J. P. Hill. *Balanoglossus*, hitherto unrecorded from Australia, has recently been met with, both at Broken Bay and at Jervis Bay, in loose sand under large stones between tide-marks. A detailed account of this interesting form, in all probability a new species, was promised.—Note on the presence of vestigial Mullerian ducts in a full-grown male lizard (*Amphibolurus muricatus*), by J. P. Hill.

ELEMENTARY PRACTICAL SCIENCE.

Elementary Course of Practical Science. Part I. By Hugh Gordon, M.A. (London: Macmillan and Co. 1893.)

IN the teaching of science, as of any other subject, the importance of method is most apparent in dealing with the elements. Of late years, since laboratory instruction has been generally introduced into our colleges, the teaching of science to advanced students may be said to be based on correct methods. But so much cannot yet be said for the teaching of the elements of science to young children. If, however, science is to obtain a recognised place in the curriculum of our primary and secondary schools, it is most important that the means adopted for the teaching of science should be educational in character. Very rarely is science so taught to young children and junior pupils in schools as to bring into active exercise the very faculties of the mind which it is supposed to develop. The teaching of science follows too closely the older education, by appealing to the memory, and storing the mind with facts and information of more or less value; and the methods employed involve a mental discipline too similar in kind to that of ordinary mathematics.

Mr. Hugh Gordon, in Part I. of his "Elementary Course of Practical Science," recently published, has broken comparatively new ground. His little book gives a very satisfactory answer to the question: How can the elements of science be so taught as to become a means of *educating* young children? In arranging a course of practical instruction in the rudiments of science, *two* principles have to be observed: first, the instruction must be introductory to science as a whole, and not to any branch of it; and secondly, the aims of the teaching must be strictly educational. In other words, the information imparted must be such as is equally applicable to physics, chemistry, and biology, and the methods must be those by which the student, at every stage of his progress, is enabled to learn by himself. Indeed, the real end of science teaching should be kept in view from the commencement of the study, and the pupil should be exercised, through his science lessons, in accurate observation, and in interpreting the results of experiments.

The book under review is the practical outcome of the experience gained by the author in superintending a course of science teaching in fifteen schools under the London School Board, and is based on a scheme drawn up by Prof. Armstrong for a committee of the British Association. Mr. Gordon has had the advantage of working for some time in the laboratory of Prof. Armstrong, to whom he very readily acknowledges his indebtedness for many valuable suggestions. The book is an endeavour to show how the most elementary science teaching may be made scientific. The author truly says: "Science had much better be left alone altogether than be taught unscientifically"; and it is only too evident that science is often so taught as to be of little or no value in the real work of education. Matthew Arnold said somewhere, "that all learning is scientific which is systematically laid out and followed up to its original sources, and that a genuine humanism is scientific." This is true, and it is because the humanistic studies have been for so many years systematically pursued, that both here and in Germany they have proved more serviceable in teaching scientific method than science itself.

The book before us is a collection of suggestions rather than a text-book or a science primer. It consists of 76 small pages, and contains a few exercises to be worked by the pupils, and for the guidance of teachers. Although an instalment only of a complete course, it indicates very fully the methods to be followed and the objects to be aimed at in teaching science to beginners. The key to the system is supplied in the question, addressed to the pupil, and constantly repeated in the text: "What is it you see? What would you expect to find if the conditions were varied?" and by the reiterated instruction: "Try it for yourself; try experiments to see if this is the case; record your results." In the method of instruction suggested by the author, the pupil is never passive; he is always doing something, and is consequently interested in his work. He is observing, recording, anticipating results, or experimenting. In dealing with the simplest matters, the methods of inductive inquiry are illustrated and practised. The teacher who follows Mr. Gordon does not instruct; he guides and assists his pupils in questioning and interpreting Nature. And although the immediate aim of this instruction is education rather than information—the development and strengthening, by suitable exercises, of certain faculties of the mind, rather than the acquisition of knowledge, the pupil nevertheless gains, in the short course here sketched out, much actual knowledge which cannot fail to prove useful in any kind of practical work. Through the experiments he is made to perform, he learns the metric system, the use of the balance, the mechanical principle of the lever, methods of determining specific gravities, the action of thermometers and of the barometer, facts concerning the expansion of solids and liquids, and applications to every-day phenomena of the principles of solubility and evaporation. Moreover, the child who has gone through this course will have learnt to be observant and accurate, and will have acquired a certain skill in the use of some of the simpler instruments of science. This is no small result of such a short course of lessons.

Between Mr. Gordon's method of teaching the elements of science, and the lectures or lessons illustrated by experiments which answer for science teaching in so many of our schools, there is the widest difference; and by showing in detail how this method may be applied, Mr. Gordon has made a very useful contribution to pedagogic literature. There is very little fault to be found in the subjects selected by the author to illustrate his method; they are nearly all such as are familiar to the pupil in his every-day life. The early and constant use of squared paper is rightly insisted on in most of the exercises. It may be thought that there is too great an advance in the difficulty of some of the exercises towards the end of the book. But possibly this may have been intentional on the part of the author, to encourage the teacher to fill in the breaks in the reasoning, and to prevent the book from being used by teacher or pupils as an ordinary text-book.

G

The book is clearly printed and illustrated, but would be improved if the numbers of the diagrams were given and referred to in the text. Where more than one diagram is found on the same page, it is not always evident to which diagram the lettering refers. The phrase "addition of interest" might also, with advantage, be changed to some other, less suggestive of commercial arithmetic. These, however, are small defects which can easily be corrected in a subsequent edition. The merit of the book is not in *what* it teaches, but in *how* it teaches; and not the least valuable part of it will be found in the introductory remarks addressed to the teachers.

PHILIP MAGNUS.

THE PYRENEES.

Les Pyrénées. Par Eugène Trutat. (Bibliothèque Scientifique Contemporaine.) (Paris: J. B. Baillière et Fils, 1894.)

IN this volume Dr. E. Trutat gives a sketch, as the full title states, of the mountains, glaciers, mineral springs, atmospheric phenomena, flora, fauna, and man in the Pyrenees, illustrated by woodcuts and diagrams, together with two small maps. The mountains differ from the Alps in their greater simplicity of structure, for they form "the most perfect type of a regular chain." Like the Alps, this consists of an axis of crystalline rocks, granites, gneisses, and schists, flanked on both sides by deposits comparatively unaltered. But there is one important difference: in the Alps, systems anterior to the Carboniferous are only recognised in the extreme east; in the larger part of the chain, rocks of that or of a later age rest on crystalline schists, which must be very ancient. But in the Pyrenees schists truly crystalline are succeeded by great stratified masses which have been much less markedly changed. The most ancient of these are assigned to the Cambrian, though as yet fossils either have not been found, or are too ill-preserved to afford any certain evidences of age. It seems, however, clear that they are older than the Silurian system, for the different members of this can be identified in several places by their characteristic fossils. The Devonian system is well developed, and followed by limestones (marine), conglomerates, and slaty rocks of the Carboniferous period. The occurrence of Permian rocks is considered by Dr. Trutat to be doubtful. Trias, of the Lorraine type, is found, followed by representatives of the various systems in orderly succession up to the Neocomian. Between this and the Cretaceous is a break, then the sequence continues till after the Nummulitic age. Then, as in the Alps, began the great series of movement, of what the present chain is the outcome. Masses of eruptive rock are connected with these disturbances. The enormous beds of conglomerate, called the *Poudingues de Palassou*, which sometimes surpass 1000 metres in thickness, recall the Alpine *nagelfluhe*. Strata partly marine, partly freshwater, represent the Miocene and the Pliocene; the Quaternary deposits presenting a general resemblance to those of the Alps.

The glaciers of the Pyrenees at the present day are comparatively small, the length of the largest not exceeding about 4300 metres, while that of the Great Aletsch is 32 kilometres, but their former extent, as in the Alps, was much greater. They filled the valleys, and even debouched on the lowland; that of the valley of Ariège must have been about 70 kilometres long. The glacial deposits have been assigned to two epochs, and Dr. Trutat claims for the earlier a considerable antiquity. In the Ariège he states that they underlie Pliocene marls, and near the plateau of Lannemezan pass under the Miocene deposits of Sansan. The sections which he gives are very rough, and further proofs of these statements, which involve obvious difficulties, are likely to be demanded. The Pyrenees owe their existence, as has been said, to post-Nummulitic disturbances, but they also afford evidence of great movements, both anterior to the Carboniferous and after the Neocomian, the latter apparently being less marked. Movements occurred after the great post-Eocene elevation, but of much less importance than they were in the Alps. The other topics, mentioned on the title-page, receive due notice, and the volume will be found useful, as it gives, in a concise and convenient form, much information about one of the most important mountain chains in Europe.

T. G. B.

OUR BOOK SHELF.

Les Courants Polyphases. Par J. Rodet et Busquet. (Paris: Gauthier-Villars et Fils, 1893.)

TO those desirous of obtaining a general knowledge of the principles used in the calculation of the efficiency and of the dimensions of polyphase motors, &c., this book will be of considerable use. In the first part, the calculation of the dimensions of, and losses in, the conductors conveying the currents are worked out at some considerable length, numerical examples being given. In the other sections the generation of polyphase currents, motors with rotating fields, and transformers are dealt with; in each case the general principles of the machines now in use being described, though no account is given of the details of their construction. There is also a short account of some of the plants for the transmission of energy by polyphase currents which have been installed, with a table summarising the tests and measurements made during the Frankfort Exhibition.

Solutions of the Examples in the Elements of Statics and Dynamics. By S. L. Loney, M.A. (Cambridge: Camb. Univ. Press, 1893.)

MR. LONEY is indebted to a friend for these solutions, and also for the revision of the whole of the proof-sheets. We have glanced through many of the examples, and they seem to be fully and clearly worked out on the whole, very little being taken for granted. Students who cannot depend on the presence of a teacher, will find that with a judicious use of this key much may be self-taught.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Sir Henry Howorth and "Geology in Nubibus."

SIR HENRY HOWORTH, in his reply to Dr. Wallace and Mr. LaTouche, concerning the excavating power of ice, remarks that he is "speaking to every man of science, geologist or

otherwise." Indeed, from the tone of his letter he would appear to be defending modern science against the attacks of certain unscientific persons who hold extreme views on glacial questions. As one who has taken a great interest in this subject for a number of years, I trust that I may be allowed to add a few words to the discussion.

We are required by Sir Henry Howorth to establish two postulates. "(1) That ice can convey thrust for more than a moderate distance. (2) That glaciers, such as we can examine and report upon, are anywhere at this moment doing the excavating work . . ." Dr. Wallace postulates.

In reply to the first, we have the undoubted fact that in hundreds and thousands of instances striated rock surfaces do occur hundreds of miles from existing glaciers. On this point he remarks: "If glaciers travelled further in former days, it was doubtless because glaciers were larger in former days, because they descended longer slopes, and had larger gathering grounds; that is to say, because the country where they grew was more elevated." So the glacial period resulted from elevation, and all glaciated regions conveniently rose together to produce it, and as conveniently sank down again. I was quite unaware that this was the accepted view. We have no proof whatever that the striated slopes down which the old glaciers moved were steeper in glacial times than they are now. Indeed, the proof is all the other way, and we may consider it as proved that at long distances from their sources, and on comparatively level plains, glaciers have moved, and have polished, ground, scratched and *grooved* the rocks over which they passed. The only point about which there may be legitimate discussion concerns the possible extent of the abrasion.

In his mechanics Sir Henry Howorth is, I am afraid, rather unsound. There are really two factors upon which the possibility of motion in a viscous body depends. One is, of course, the slope of the surface over which it passes, and the other is the slope of the upper surface of the viscous body. Fracture and regelation have little to do with the question, for fracture only occurs near the surface, and fracture must not be confounded with *shear*. Sir Henry Howorth makes one statement which seems to account for the conclusions he has come to. It is "a viscous body, unless the viscosity approaches that of a liquid, cannot move by mere hydrostatic pressure." In fact he assumes, without adducing a particle of evidence in support of the assumption, that there is an inferior limit to the stress required to deform *glacier* ice. I always regarded viscosity as something which retarded motion, but did not in any way interfere with the ultimate result. I have personally made mechanical tests of ice, and also of many thousands of samples of steel, iron, copper, brass, tin, &c. All these substances yield elastically and permanently under stress, some of them under very small stresses, but ice is the only one of them that yields continuously from the moment the stress is applied until it is again removed.

It is not, properly speaking, pressure from behind that forces the ice forward. Ice being viscous, every individual particle moves in the direction of least resistance at a rate depending upon the stress and the viscosity. Sir Henry Howorth may term this "Geology in Nubibus," and call it unmechanical; but I would point out to him that I regard the question from the point of view of a *mechanical engineer*, which I am afraid he does not.

During the past summer I had the pleasure of seeing some of the Norway glaciers, and also of crossing the Folgefond snow field. It was interesting to note that although the streams coming from the hills and uplands free from ice were quite clear, those escaping from the glaciers were charged with sediment. In this connection I would call attention to a calculation made by Prof. G. F. Wright, giving the rate of erosion of its bed by the Muir Glacier. From the volume and turbidity of the water he makes the figure one-third of an inch per annum over the whole of the 1200 square miles of area occupied by the glacier. In fact, erosion goes on much more rapidly when the rocks are covered by moving ice than when they are not. Although we may feel absolutely certain, both by fact and reason, that the erosion beneath glaciers when they are moving with relative rapidity is very great, and be as sure as we reasonably can be of most things that such erosion must result in the formation of lake basins, I am afraid that we shall be unable to satisfy Sir Henry Howorth on the point. We cannot remove a glacier, and if there should prove to be a rock basin below measure of its depth, then replace the ice, and measure again, say, in a thousand years. This is the kind of proof the second postulate seems to demand. R. M. DEELEY.

The "Zoological Record."

IN reference to the letter of Messrs. Pocock and Bather, on the subject of the *Zoological Record*, in NATURE of November 16, I desire to state that the council of this Society (to which the *Zoological Record* at present belongs) quite agree with the above-named gentlemen in their wish to render the *Zoological Record* more complete by combining palæozoology with it. With this view the council some time since addressed the Geological Society, and suggested what in their opinion would be an equitable arrangement for carrying out the plan. This arrangement, however, as will be seen by the copy of the correspondence enclosed herewith, was rejected by the council of the Geological Society. It remains, therefore, for Mr. Bather and such members of the Geological Society as may share his sentiments, to do their best to induce the council of the Geological Society to alter their views upon this question.

I have good authority for stating that the editor of the *Zoological Record* is not really of a different opinion to Messrs. Bather and Pocock on this subject, as would seem to be inferred in their letter. I believe that he only suggested that the palæontologists should start a record for themselves because of the refusal of the Geological Society to co-operate with us in our work. P. L. SCLATER.

Zoological Society of London,
3, Hanover Square, London, W.

(COPY.)

To the Secretary, the Geological Society, Burlington House, W.

DEAR SIR,—I am instructed by the council of this Society to apply to the council of the Geological Society under the following circumstances:

When the *Zoological Record* (which is now carried on by this Society) was established twenty-eight years ago, it was not considered that palæozoology came within its scope, and the recorders were instructed to notice only such palæontological works as appeared to be "of interest to the student of living forms" in their records. This part of the subject has, however, received a continually increasing amount of attention from the recorders, and the council of this Society, being desirous that palæozoology should in future be treated of in the *Record* as completely as recent zoology, asks the assistance of the Geological Society in carrying out this object.

The Zoological Society bears at present a loss of about £350 per annum, arising from the publication of the *Zoological Record*, and, as the inclusion of palæozoology in an exhaustive manner would materially increase the work of the recorders, and necessitate an addition to their remuneration (which is even at present too small), the council of this Society asks the council of the Geological Society to make a grant of £100 annually towards the expenditure thus incurred.

It is thought by some members of the Council that the Zoological Society, bearing, as it does at present, the whole loss arising from the publication of the *Record*, should not increase its expenditure thereon, and the sum mentioned above, £100, would, it is estimated, be sufficient to relieve this society from the additional expense that the inclusion of palæozoology, in its record of zoological literature, would involve. In return for this assistance, the council of this Society will make every effort to treat the subject of palæozoology exhaustively, and will add to each *Record* a reference to palæozoological memoirs stratigraphically arranged, besides dealing with those memoirs in detailed analysis in the systematic records.

In order that the interests of palæozoology may be more carefully attended to, the council of this Society will undertake to place a nominee of the Geological Society upon the committee of their body appointed every year to supervise the publication of the *Zoological Record*.

Should these proposals meet with acceptance from the Geological Society, the council will further undertake to place one hundred copies of the *Zoological Record* at the disposal of the Geological Society, and, if it be wished, will alter the title of the *Record* to *The Record of Zoological and Palæozoological Literature*, from *The Record of Zoological Literature.*

Trusting that these proposals will meet with the approval of your council, I am, dear sir,
Yours faithfully and obediently,
(Signed) P. L. Sclater,
January 21, 189 Secretary.

(Copy.)

From the Geological Society, Burlington House, W.

Dear Sir.—Your communication, dated January 21, 1893, was this day submitted to the council of the Geological Society, and I was asked by the council to inform you that they regretted that they were unable, in the present state of the Society's income, to recommend to the Fellows of the Geological Society an increase of expenditure such as would be necessitated by acceding to your request that a grant of one hundred pounds should be made to aid the publication of the *Zoological Record*.

Whilst regretting their inability to comply with your request, the council thank you for the conditional offer which accompanied it. I am, dear sir,
Yours faithfully and obediently,
(Signed) John E. Marr,
February 22, 1893. Secretary.

The Proposed Continuous Polar Exploration.

Your excellent summary of the proposed continuous Polar exploration (November 2, p. 18) conveys a wrong impression in its closing sentence. The system may in the future assume large proportions; but the *beginning*, to be made next year, *will be very small*. It will consist merely in the establishment of the principal station at the south-east angle of Ellesmere Land, and 80 days' exploration along the west coast of that land. At most, an advanced depôt, erected some 100 miles farther west, may be so fitted out as to serve at once as a secondary station. It is not easy to see why this work should be postponed till Peary and Nansen have returned. Their fields are far from ours, and their results can shed no light on the area west of Ellesmere Land. As well might you say that the exploration of the Mediterranean should not be begun until that of the Baltic was completed.

As you say, the possibility of continuous Polar exploration is not demonstrated. There can be no doubt, however, of the value of a permanent station at the entrance of Jones Sound, nor of the practicability of its maintenance, so long as the whalers continue to visit that region. How far exploration may be carried with that station as a base, it is impossible to foretell, but at any rate the existence of a secure base will be an advantage possessed by no previous expedition in that direction, and, in the words of the "Encyclopædia Britannica," will "make disaster on a large scale, humanly speaking, impossible."

U.S. Geological Survey. Robert Stein.

On the Classification of the Tracheate Arthropoda.—A Correction.

In No. 423 of the *Zoologische Anzeiger* (1893) I ventured to propose a new classification of the Tracheata, including under this heading those Arthropoda that are usually known as myriopods and insects. The principal changes suggested were the abolition of the name Myriopoda as indicating an unnatural assemblage of beings and the union of the *Chilopoda*, *Symphyla*, and *Hexapoda* in a division (Opisthogoneata), which was based upon the situation of the generative apertures at the hinder end of the body. But in referring the *Symphyla* to this category by adopting the assertions of Menge and Latzel respecting the position of the orifices in question, it appears that I fell into error; for Dr. Erich Haase has kindly written to me from Bangkok, with the information that by means of a series of transverse sections he was able, although with considerable difficulty, to confirm Grassi's statement to the effect that the generative apertures in *Scolopendrella* are situated upon the fourth body-segment. This genus is therefore progoneate, like the Diplopoda and Pauropoda; but whether it should be ranged with these two classes, or occupy an independent position between the Progoneata and Opisthogoneata, is a question for future discussion.

R. I. Pocock.

THE LOSS OF H.M.S. "VICTORIA."[1]

II.

We dealt last week with the circumstances relating to the loss of H.M.S. *Victoria*, and the causes of her sinking with such startling rapidity after she was rammed. The facts, so far as they are known, are fully and, in our opinion, fairly summarised by Mr. W. H. White, in No. 3 of the Admiralty Minutes, just issued; and Mr. White demonstrates clearly, from the results of calculations made in the Construction Department of the Admiralty, that the movements and behaviour of the ship after the accident, and the observed effects upon her line of flotation and her stability, are precisely what would be caused by the entry of water into the compartments at the fore end of the ship, which are known, or believed, to have been filled before she foundered. These calculations serve, therefore, the useful purpose of showing that the water known to have entered those forward compartments that were proved, by evidence given before the Court Martial, to be filled, was quite sufficient to account for the subsequent capsizing and sinking of the ship; and for the capsizing and sinking to happen exactly in the manner that was observed. This is so, as already stated, whether Mr. White be absolutely right or not with regard to the precise state of each separate compartment after the damage; as the evidence is sufficiently conclusive, upon the whole, respecting the various compartments, to reduce the probability of error to a very small amount, such as would not materially affect the practical results of the demonstration.

The Admiralty calculations thus remove all reasonable doubt as to whether the compartments known to have been filled were sufficient in themselves to account for the final disaster; and they make it unnecessary, in order to explain what happened, to speculate as to the probability of the collision having been more far-reaching in its effects upon the structure, or internal arrangements, of the ship than the evidence indicates. The evidence, as it stands, is shown to completely account for the facts; and to furnish a solid basis for investigation, or argument, as to the lessons that may now be learned from the loss of the *Victoria*.

The Lords Commissioners of the Admiralty, in the first of the three Minutes lately issued, dated October 28 last, on the finding of the Court Martial, stated that the question of closing the water-tight doors of the *Victoria*, and the construction and stability of the ship, would be dealt with separately. Their lordships accordingly issued the second Minute, dated October 30. This Minute states that, in consequence of the Court Martial finding "that it does not feel itself called upon, nor does it feel itself competent, to express an opinion as to the causes of the capsizing of the *Victoria*," their lordships instructed the Director of Naval Construction to make a thorough examination and analysis of those parts of the evidence which throw light on these points. The report prepared by Mr. White, in accordance with these instructions—No. 3 of the present Minutes—was dealt with in our article of last week; but we then left over for subsequent consideration the references made in the Minutes to the lessons taught by the various circumstances of the case.

These points being dealt with authoritatively in the second Admiralty Minute, dated October 30, we shall deal principally with that Minute in the following remarks. It commences by adopting the figures and the conclusions stated in Mr. White's report with regard to the nature of the blow received by the *Victoria*, the after movements and behaviour of the ship, the extent to which water found access into her, and the effect of such water upon her flotation and stability. We have nothing

[1] Continued from p. 104.

further to say upon the subjects dealt with in this portion of the Minute, which appears to accord with the evidence, and also with the known effects that would be produced by filling the compartments that were opened up directly to the sea, or into which water could pass freely through open doors, hatches, &c.

The Admiralty Minute next expresses the opinions of the Board upon the following points; and we will take these in the order named in the concluding paragraph of our former article: (1) The effect of longitudinal bulkheads upon the capsizing of the ship; (2) what would probably have happened if the doors and ports in the upper-deck battery had been closed; (3) what would probably have happened if all doors, hatches, &c. had been closed before the collision took place; (4) the efficiency of the water-tight doors to the bulkheads, and the means of closing them quickly; (5) the value of an armour belt at the ends for resisting damage; (6) the sufficiency of the stability possessed by the ship; and (7) the steps that should be taken "to prevent the recurrence, under similar circumstances, of the conditions which, after the collision, resulted in the loss of the ship."

1. *The effect of longitudinal bulkheads upon the capsizing of the ship.*—Mr. White points out that there was no continuous central longitudinal bulkhead in the *Victoria*. In the stokeholds and engine-room there were two such bulkheads on opposite sides of, and each several feet from, the centre line; but these were far abaft the damaged portion of the hull, and do not appear to have been reached by water that entered the ship up to the moment of sinking. There were a few longitudinal partitions in the fore part of the ship; but some of these were inoperative because of damage or open doors. The effect of filling the compartments formed by these longitudinal partitions has been calculated, and it is stated that this would only cause an inclination of about 5° in the intact condition of the ship. This result does not, however, bear directly upon the actual effect produced in such circumstances as are being considered, because the damage caused by collision not only admitted water into the ship, but it reduced, at the same time, her power to withstand the heeling effect of the excentric compartments that were thereby filled. The ship would only have heeled about 5° with these compartments filled, if the hull had been uninjured; but if the hull had been uninjured, the compartments would, of course, not have been filled. Mr. White goes on to say: "It appears on investigation that in the damaged condition and at the extreme position which the *Victoria* occupied before the lurch began, the flooding of the compartments enumerated, and the accumulation of water on the starboard side, account for the observed angle of heel, 18 to 20 degrees." This inclination—which is what was really due, in the circumstances, to water being held over to starboard by the longitudinal partition above referred to; as the accumulation of other water to starboard was merely the consequence of the heeling thus caused—must have allowed the sea to enter the ports and door of the upper deck battery sooner than it otherwise would have done, and thus have hastened the capsizing of the ship. The Admiralty Minute states that "the evidence clearly shows that the existence of longitudinal water-tight bulkheads in the *Victoria* was not the cause of her capsizing. There were only a few minor longitudinal partitions in the fore part of the ship. Many of these were inoperative because of damage or open doors."

This conclusion is doubtless correct so far as it relates to the continuous longitudinal central bulkhead to which the capsizing of the ship was prematurely, though confidently, attributed by certain hasty critics, because such a bulkhead did not exist in the forward part of the ship that was affected by the collision. It clearly does not apply, however, to the minor longitudinal partitions above referred to, because these must have been contributory to the disaster according to the extent by which the water they held over towards one side caused the heel of the ship to increase as the bow became immersed, and the stability diminished. It is a question that could only be settled by further investigation, whether the reduction of stability and the heeling effect thus caused was greater or less in this particular case than would have occurred if the water had been free to pass from side to side of the ship within the fore-and-aft limits of the compartments it entered.

2. *What would probably have happened if the doors and ports in the upper-deck battery had been closed.*—Mr. White says: "It is not possible to state absolutely that the *Victoria*, with turret and battery closed, could have been kept afloat permanently under the actual circumstances of the collision"; and he points out that there are many compartments into which water might have found its way eventually, through doors and hatches that were probably open. He considers, however, that "her capsizing would have been improbable even if she had eventually foundered." The Admiralty endorse this opinion in their minute, which states: "The great weight of water thus gradually admitted into the forward part of the ship might eventually have caused the ship to founder by the head."

We see no reason to believe that the ship could possibly have been saved by the closing of these doors and ports. By the time the sea had reached them the fore end of the ship was so deeply submerged, and there were so many openings by which water could then find its way into compartments not already filled, that it is difficult to conceive how even the rate at which she was so rapidly sinking could be checked. When the sea had reached the height of the turret ports and the upper-deck battery ports and doors, the ship was inevitably doomed. She might possibly have sunk by the head without capsizing, although this appears improbable. With her stability reduced to the extent described in the Admiralty Minutes, when the bow was under water, and the heel to starboard was great, it would appear that the effect of the increasing quantities of water in the ship would certainly be to capsize her very soon. But whatever might have been the precise manner in which she would have gone down, there appears no doubt that the vessel would have gone to the bottom almost immediately after she did, even if the turret and upper-deck battery ports and doors had been closed.

3. *What would probably have happened if all doors, hatches, &c., had been closed before the collision took place.*—We agree upon this point with the opinion, based upon the calculations of the Construction Department, which is expressed in the Admiralty Minute as follows: "While the loss of buoyancy must in that case have been considerable, yet, making all due allowances for probable damage, the ship would have remained afloat and under control, and able to make port under her own steam. Her bow would have been depressed about to the water level, her heel to starboard would have been about one-half of that observed before the lurch began (*i.e.* 9 or 10 degrees), her battery ports would have been several feet above water, and she would have retained ample stability."

4. *The efficiency of the water-tight doors to the bulkheads, and of the means of closing them quickly.*—This question is one of the greatest importance in the present case, because, as we have seen, the *Victoria* might apparently have been navigated safely into port if all the water-tight doors, hatches, &c. had been closed soon enough to prevent water passing from compartments directly opened up by the collision into others from which they were separated by water-tight bulkheads or decks. The Admiralty expresses strong and unqualified opinions upon this point. Their lordships say "the detailed evi-

dence establishes the fact that water-tight doors, hatches, &c. in the *Victoria* were in good order. It contains nothing which suggests a doubt of the efficiency of the system of water-tight subdivision existing in the *Victoria*. At the parts affected by the collision the subdivision was minute, but doors were left open. According to the established practice of the Admiralty in all classes of ships, the number of water-tight doors is made as small as possible consistently with the essential conditions for working and fighting the ship. . . . In conclusion, their lordships are of opinion that . . . . the arrangements of water-tight doors . . . . did not by any fault of principle contribute to the loss of the ship; but that, on the contrary, had the water-tight doors, hatches, and ports [1] been closed, the ship would have been saved." Mr. White says, in his Minute: "No orders were given to close doors until one minute before collision. It is established by the evidence that the doors, &c. were in good order. The failure to close doors, therefore, was due entirely to the insufficiency of the time available, especially in compartments breached by the collision."

The statement that the water-tight doors, hatches, &c. were in good order at the time of the collision appears justified by the evidence; except, perhaps, with regard to the door at the after end of submerged torpedo room, which slides horizontally, and could only be moved six or eight inches when the attempt was made to close it after the collision. Their lordships go on to say that the detailed evidence contains nothing which suggests a doubt of the efficiency of the system of water-tight subdivision. We cannot discover, however, that this question was investigated by the Court Martial. Very complete evidence was obtained as to the exact state of each compartment, and of each opening into the compartments, at the time of the collision; but the general question of the efficiency of the system of water-tight subdivision, which involves that of the water-tight doors and hatches to the various compartments, was not gone into. It would appear, indeed, to have been expressly excluded from the investigations of the Court Martial, since it can only be judged in relation to the buoyancy and stability of the ship; and the Court confined itself, as already stated in the quotation given from the Admiralty Minute, to placing upon the Minutes all evidence obtainable with regard to the closing or otherwise of water-tight doors, &c., but did not feel itself called upon, nor feel competent, to express an opinion as to the causes of the capsizing. While it may therefore be true that the evidence contains nothing which suggests a doubt upon these points, it is, on the other hand, equally true that it contains nothing which proves the assertion that the system of water-tight subdivision was efficient.

One of the weak points in the water-tight subdivision appears to have been the doors and hatches to openings in the bulkheads and decks; and especially the impossibility of closing a sufficient number of them after the collision to keep the ship afloat. The doors upon the mess deck were all closed; but this deck was about 3 feet above the water-line, and there was time to attend to the doors upon it before the inrush of water drove the men away. On the protective deck below, however, and on the platform in the hold, there was not time to get at all the doors and hatches before the water reached them; while most of those that were got at and closed appear to have been only partially, and very imperfectly, secured. The plans of H.M.S. *Victoria*, appended to the Admiralty Minutes, show ten water-tight doors in the bulkheads on the protective deck, at the fore side of the armour belt. This deck is about 100 feet in length, and includes the whole of the area directly affected by the collision; and there is only one important bulkhead in this space which does not contain a door, viz. that which divides the cable locker from the fresh-water tanks. On the platform in the hold, immediately under the protective deck, there are eight water-tight doors in the bulkheads, while there is in addition a water-tight door in the bulkhead at Frame Station 35, which forms the after boundary to the space. This was the door which could not be closed when the attempt was made to do it. There is no bulkhead upon this deck in the space referred to which does not contain a door. Besides these doors there are numerous openings, fitted with water-tight hatches, in the decks over the various compartments.

The Admiralty Minute states that the number of water-tight doors was made as small as possible, in accordance with the established practice of the Admiralty. It would be difficult, however, to fit more doors than are shown upon the plans of the two decks that are below the water-line in the *Victoria*—the protective deck and the deck below it in the hold.

Judging by the Admiralty plans, it was only a certain number of these water-tight doors that were fitted so as to slide horizontally; and some were merely hinged doors, which could only be closed by entering the compartment in which they were situated, and were secured by a number of clips round the edge of the door. Some of these were upon the most important transverse bulkheads, such as the two bulkheads which enclosed the submarine mining flat on the platform in hold. We have always considered that arrangements should be made for closing all doors in bulkheads that are essential to the efficient water-tight subdivision of the ship from a deck that is at a safe height above water, as well as in the compartments where the doors are; and we believe, also, that this is the Admiralty rule—as it obviously ought to be. If doors are fitted below the water-line so as only to be opened or closed in the compartments where they are, they should seldom require to be opened, and never to be left open, unless the bulkheads to which they are fitted are not considered essential to the efficiency of the water-tight subdivision. It does not appear by the evidence, or by the Admiralty Minutes, that a single one of the many doors in the fore part of the ship on and below the protective deck could be closed from a deck at a safe height above water; because the sliding doors could only be closed, we believe, from the main deck, which does not appear to have been more than 3 feet above water at the time of the accident, and was almost instantly immersed. In view of these circumstances we cannot agree with the opinion of the Admiralty that there is "nothing which suggests a doubt of the efficiency of the system of water-tight subdivision existing in the *Victoria*. It appears, upon the other hand, quite practicable to improve the efficiency of this system by dispensing with some of the doors, and by arranging with reference to the others that every one which requires to be left open for even an instant, without the certainty of some one being in constant attendance upon it till it is closed, should be capable of being worked from a deck at a safe height above water.

Mr. White says that the failure to close the water-tight doors in the forward part of the *Victoria* has caused suggestions to be made that automatic or self-closing doors should be adopted instead of existing arrangements. This suggestion was, he adds, carefully considered long ago, after certain experimental doors had been tried. He is satisfied that the existing arrangements are the best, and that their safety is only a question of good time being allowed for closing the doors. It must be remembered, however, that when doors can only be closed in the compartments where they are situated, and these are below the water-level, the inrush of water would often effectually prevent the closing of the doors in bulkheads that separate the compartment that is breached from those

[1] It has already been pointed out that the closing of the ports would apparently have had but little effect, and the Admiralty admit that the ship might still have foundered.

adjacent to it. Also, with such arrangements below as those of the *Victoria*, it is impossible to ensure that an unforeseen accident would always allow of sufficient time to close the water-tight doors in the manner required.

The efficiency of the water-tight hatches, and the chances of their being properly secured in an emergency when they are fastened by a number of clips round the edge, as at present, is also a question that appears to require consideration; while it is to be observed that the sliding horizontal door in the protective deck of the *Victoria*, which opened into a shoot through which coal was trimmed from the reserve bunkers at after end of protective deck, into the side bunkers in the stokehold, could not be closed from the shoot in which the men worked who were trimming the coal; but had to be worked from the submerged torpedo room, a compartment below the protective deck. This open door had an important effect upon the capsizing, for Mr. White states that "one of the chief causes of inclination to starboard is to be found in the fact that, owing to open doors, water was able to find its way from bunkers above the protective deck, down through the coal-shoot, and so to fill No. 7 bunker just before the forward starboard stokehold."

It appears to us that one of the chief lessons taught by the circumstances of this disaster, is the necessity of reducing the number of water-tight doors and hatches, and of arranging that all of them which are essential to the efficiency of the water-tight subdivision, and are ever likely to be left without attendance while open, should be capable of being closed, either by a thoroughly satisfactory self-acting arrangement, or by appliances for working them from a deck at a safe height above water.

The points still remaining to be considered will be reserved for our next article.

FRANCIS ELGAR.

REAPPEARANCE OF THE FRESHWATER MEDUSA (LIMNOCODIUM SOWERBII).

FOR three years nothing has been seen of the freshwater medusa in the Regent's Park, and naturalists had given up hope of carrying on any further investigation into its life-history. It seemed as though this beautiful little organism—brought we know not how or whence into the midst of London—had, like some mysterious comet, unexpectedly burst on the zoological world, and as unexpectedly disappeared.

I was, therefore, greatly astonished to hear in September, from my friend the Director of Kew, that the curator of the Sheffield Botanic Gardens (Mr. Harrow) had discovered it in quantity in the Victoria Regia tank under his care during the present summer, and I was soon after delighted by the safe arrival from Sheffield of a bottle containing living well-grown specimens of the familiar jelly-fish. Mr. Harrow informs me that he observed it in the tank at Sheffield for the first time in the beginning of June of this year (1893). Specimens were still observed as late as the middle of October—giving a duration of some fourteen weeks—an unusually long period. Mr. Harrow estimates the total number seen as at least 300.

The last seen in the Botanic Gardens, Regent's Park, London, were taken from the *new* Victoria Regia tank on July 30, 1890. The question as to how the jelly-fish got to Sheffield is easily answered. Water plants (Nymphæaceæ and Pontederia) were sent (as I am informed by Mr. Sowerby and by Mr. Harrow) from Regent's Park to Sheffield to re-stock the tank there on April 4, 1892, and on April 7, 1893. Hence there was the probability of some of whatever reproductive germs of Limnocodium existed in Regent's Park being transferred to Sheffield. The curious thing is that in 1892 and in 1891 no Limnocodium were seen in the original source—viz. the Regent's Park tank—nor in 1893, excepting a few sent from Sheffield and placed in that tank by Mr. Sowerby.

This is the first instance recorded in which another Victoria Regia tank has been "infected" with Limnocodium from the original Regent's Park tank, excepting when the new tank in Regent's Park was in 1890 infected from the old one—by the transference to it of weeds and roots containing the germs of the jelly-fish.

The tank at Kew has never been properly infected, for it is, I regret to say, the anti-zoological custom at the Royal Gardens to thoroughly cleanse, wash, and furbish up the Victoria Regia tank every year so thoroughly that the winter germs of the jelly-fish are removed or destroyed. Hence Limnocodium has flourished at Kew when sent there from Regent's Park, but has never "carried over" from one season to another. It is, fortunately, the custom in other botanical gardens to leave a quantity of "sludge" (including some old leaves and stems) at the bottom of the tank, when the water is drawn off and the soil prepared for a new season, and hence Limnocodium has been preserved from destruction for so many years.

As to what is the precise nature of the process by which Limnocodium has been carried over from one season to another in the Regent's Park, we are still uncertain. The facts at first ascertained were these, viz. that the jelly-fish suddenly appear each year as early as April or as late as August, and remain for from five to twelve weeks, when they die down and absolutely disappear. During the first few weeks of their appearance the water is found to contain an immense number of minute young forms ($\frac{1}{30}$ of an inch in diameter), which I described and figured in the *Quart. Journ. Micros. Science*, vol. xxi. p. 194. Evidently these young were being produced in quantity in the tank, and gradually developed to the full size of half an inch diameter. The form and appearance of these young were such as to lead me to the conclusion (subsequently found to be erroneous) that they had been developed from eggs. At the same time the remarkable fact was established by the examination in successive years of many hundred specimens that the adult *Limnocodia* were every one, without exception, males. They produced abundant motile spermatozoa, but not a trace of an egg-cell was ever found in any one of them!

The hypothesis which I entertained in 1884 as an explanation of this curious state of things was—that the female was a non-motile, perhaps a fixed hydriform organism, and I accordingly searched for such a form in the mud and *débris* from the bottom of the tank. At last, in a large quantity of such material which I obtained when the tank was cleared out in the winter of 1884, my assistant, Dr. A. G. Bourne, found a very strange diminutive polyp adhering in numbers to the root-filaments of Pontederia. This polyp he carefully described in the same year in a communication to the Royal Society. There was very great probability that this little polyp, devoid of tentacles, and not more than $\frac{1}{8}$th of an inch long, was the "trophosome" of the Limnocodium medusa. That this was a true inference was subsequently proved by Dr. G. H. Fowler, who in 1890 (*Quart. Journ. Micros. Science*, vol. xxx.) the last year in which the jelly-fish were seen in London, showed that the little spherical young found floating in the water of the tank are nipped off by a process of transverse fixion from the free ends of the minute polyps described by Bourne.

Fowler (whose observations were made in my laboratory in 1888) found the polyps very abundantly upon floating water-plants widely scattered in the tank; they were also detected by Mr. Parsons, of the Quecket Club, in water which was the overflow of the tank, and accumulated in an outside reservoir.

The immediate question then became "How do the polyps originate?" The polyps account for the medusæ,

but whence do they themselves originate? And this question still remains unsolved. The polyps are observed to increase by budding, but they never form clusters of more than four "persons." How do they become distributed over the under surface of nearly all the floating leaves in the tank? How do they get carried to an outside reservoir? Is it not improbable that they would continue year after year to propagate themselves by budding as polyps, and in the summer to throw off successive crops of *male* medusæ? It is possible that this is the whole history, but not quite probable.

In any case, however, the existence of the minute polyps attached to water-plants is sufficient to explain the introduction of the jelly-fish to Sheffield. It also is sufficient to explain the original introduction of the jelly-fish to the Regent's Park, since in 1878 (two years before the first discovery of the jelly-fish) specimens of a remarkable water-plant (*Pontederia*) were brought from Brazil by a lady and presented to the Botanical Society, and placed in the Victoria Regia tank.

A new interest has recently been added to that already attaching to Limnocodium by the description of another fresh-water jelly-fish, the *Limnocnida Tanganyisicæ*. This remarkable form was worked out in my laboratory in Oxford during last winter by Mr. R. T. Günther, who received the specimens from his father, Dr. Günther, F.R.S., of the British Museum. Dr. Günther had written to the Mission on Lake Tanganyika in order to procure the specimens. Individuals of three kinds are described by Mr. Günther, viz. males, females, and a-sexual individuals which produce crops of buds on the manubrium (see his papers in the *Ann. and Mag. Nat. Hist.*, 1893, and in the forthcoming number of the *Quart.-Journ. Micros. Science*). Whilst differing greatly from Limnocodium in most respects, Limnocnida agrees with it, in a most extraordinary way, in the minute structure of the marginal sense-organs. No light is thrown by Limnocnida on the problem of the life-history of Limnocodium.

I subjoin a list of dates in reference to the history of Limnocodium, and may add that the columns of NATURE already contain numerovs communications relative to it, viz. in vol. xxii. (1880), pp. 147, 177, 178, 190, 218, 241, 290, and in vol. xxxi. p. 107.

1880.—June 10, first observed in Regent's Park; remained six weeks.
1881.—June 12; reappeared; remained five weeks.
1882.—None observed.
1883.—April 28; twelve weeks.
1884.—April 27; twelve weeks (?).
1885.—April 5 (no record of duration).
1886.—August 7 (no record of duration).
1887.—End of May (no record of duration).
1888.—May 10 (no record; very few observed).
1889.—None.
1890.—New tank constructed and stocked; July 10 a few.
1891.—None.
1892.—None. Plants sent to Sheffield April 4.
1893.—None in London. Plants again sent, April 7, to Sheffield.
1893.—June 7 to mid-October, large numbers observed in tank at Sheffield.

Hydroid trophosome discovered by Bourne in winter of 1884.
Production of medusæ by hydroid, observed by Fowler, in May, 1888.

E. Ray Lankester.

DEATH OF PROF. TYNDALL.

ANOTHER of our "Scientific Worthies" has "crossed the bar," leaving behind an honoured name and works that will perpetuate his memory. On Monday evening Prof. Tyndall passed away at his residence, near Haslemere. For some time previous he had been suffering from insomnia and rheumatism, and very unfavourable symptoms set in on Monday morning. He quickly became unconscious, and except for a brief interval at midday, remained in this state until half-past six o'clock, when a peaceful change from life to death took place. It appears that the cause of death was an overdose of chloral, which Prof. Tyndall took as a sedative against insomnia. He had been in the habit of taking narcotics for several years past in order to overcome the sleeplessness from which he suffered. On Monday about the usual quantity was administered to him, but his greatly weakened condition was unable to bear so much. The inquest on the body, which was considered necessary by the doctors, was held yesterday.

A detailed account of Tyndall's life was given in these columns in August, 1874, so it is only necessary to trace now a brief outline of his career. He was born in 1820, at Leighlin Bridge, near Carlow, in Ireland. But it was not until 1847 that he began his career as a teacher of science, by accepting a post in Queenwood College, Hampshire, where Dr. Frankland was chemist. A year later the two friends did what every young man of science should do, if possible—they went together to a German University, the University of Murburg, Hesse Cassel, rendered celebrated by Bunsen and others; and to Bunsen, whose lectures he attended, and in whose laboratory he worked, Tyndall was never tired of expressing his obligations. He was at Murburg when Knoblauch, preceded by a distinguished reputation, and accompanied by a choice collection of instruments, went there as Extraordinary Professor. Subsequently, in conjunction with Knoblauch, Tyndall carried on his "classic" inquiries in connection with diamagnetism, afterwards prosecuting his research in the laboratory of Prof. Magnus at Berlin. In 1851 his life-long friendship with Prof. Huxley commenced, and in the following year he was elected a Fellow of the Royal Society. In February, 1853, he gave the first of his eloquent Friday evening lectures at the Royal Institution. Shortly afterwards, at the proposal of Faraday, he was appointed Professor of Physics in the Institution, a post from which he retired in 1887. The managers and members of the Institution marked their sense of the benefits he had conferred upon it by electing him as Honorary Professor, a title previously borne by Davy and Brande, and by calling one of the annual courses of lectures "The Tyndall Lectures." His bust was also placed in the Institution in memory of his relations with it.

A complimentary dinner was given to Tyndall on the occasion of his retirement from the Chair of Physics in the Royal Institution. The body of eminent men which met at the dinner was such as has seldom if ever been brought together to do honour to a man of science, and when the chairman, Sir George Stokes, the then President of the Royal Society, gave voice to the desire of the company that their guest should long enjoy the leisure which he had so well earned, it was not thought that after but six years of rest from labour he would be called away. The speeches made at the dinner are reported in NATURE, vol. xxxvi. p. 222, and they show the high regard in which Tyndall was held throughout the world of science, art, and letters. In responding to the toast of the evening, he gave an account of his life, including in his speech the following true remarks:—"To keep technical education from withering, and to preserve the applications of science from decay, the roots of both of them must be imbedded in the soil of original investigation. And here let it be emphatically added, that in such investigation practical results may enter as incidents, but must never usurp the place of aims. The true son of science will pursue his inquiries irrespective of practical considerations. He will ever regard the acquisition and expansion of natural knowledge—the unravelling of the complex web of nature by the disciplined intellect of man, as his noblest end, and not as a means to any other end." This was the kind of spirit that actuated Tyndall throughout his career. It

was well shown in 1872, when he placed the balance of 13,000 dollars, that remained after his lecturing tour in the United States, in the hands of a committee who were authorised "to expend the interest in aid of students who devote themselves to original research."

It would be superfluous for us to enumerate Tyndall's explorations in the domain of science, or to expatiate upon his remarkable power of presenting a subject both in speech and in writing, for among men of science these facts are common knowledge. To such men as he—not only original discoverers, but also popular and powerful interpreters of scientific fact—we owe much of the advancement that has been made during the last forty years.

NOTES.

MR. H. H. TURNER, of Greenwich Observatory, has been elected to the Savilian Professorship of Astronomy at Oxford, in succession to the late Prof. Pritchard.

THE Russian traveller Potanin, who has spent more than a twelvemonth in a botanical exploration of Thibet, is expected in St. Petersburg in January next. M. Dobrotworsky has arrived at Jenisseisk on the Jenissei, on a botanical expedition.

PROF. BEN. K. EMERSON, of Amherst College, and of the U.S. Geological Survey, who met with a serious railroad accident last summer, and was reported killed, has so far recovered that he started in November on a trip round the world, for rest and recuperation. He visits Italy, Egypt, India, Java, and Japan. Prof. Emerson has been engaged for a long time in mapping the crystalline rocks of Central Massachusetts and Connecticut.

DR. NICOLE has been appointed Director of the Bacteriological Institute of Constantinople.

DR. SEUBERT has been appointed Professor of Analytical and Pharmaceutical Chemistry in the University of Tübingen.

MR. W. F. C. GURLEY has been appointed Director of the Geological Survey of Illinois.

WE learn that Prof. D. A. Gilchrist has accepted the Professorship of Agriculture at the University Extension College, Reading.

DR. K. VON DALLA TORRE has been appointed Professor of Botany in the University of Innsbrück, and Dr. H. Möller Professor of Botany in the University of Greifswald.

MR. W. T. MCGEE, known for his contributions to geology, has been appointed Director of the Bureau of Ethnology at Washington, U.S.

THE Chair of Comparative Anatomy and Zoology in the Biological School of the University of Pennsylvania has been accepted by Prof. E. D. Cope, and that of Geology and Mineralogy by Prof. A. P. Brown.

THE death of Dr. Webb, the well-known Principal of the Aspatria Agriculture College, is a severe loss to agricultural education. After a very brief illness, he passed away on November 28, in the prime of life. Through his exertions the College at Aspatria has been raised from a very low condition to its present high standing. He was greatly respected by his students, and his place as a teacher of agriculture will not be easily filled.

THE first step towards the introduction of the decimal system into Russia will be taken on January 13, 1894, when, by order of the Czar, the chemists of the Russian empire will begin to use decimal weights and measures.

A PRIZE of 1800 liras is offered by the Italian Geological Society for the best account of the state of knowledge of Palæozoic and Mesozoic formation in Italy, the work to be in continuation of D'Archiac's "Histoire des progrès de la Géologie," and to be presented before the end of March, 1896.

Die Natur announces that the Berlin Academy of Sciences has granted Drs. Richarz and Krygar-Menzel two thousand marks for the carrying on of their investigations of the constant of gravitation. A like sum has been granted to Dr. Franz Reinecke for the furtherance of his ethnological and anthropological studies.

THE ninth congress of Russian Naturalists will be opened at Moscow on January 15, 1894. The Mathematical and Physical Faculty of the Moscow University has undertaken its organisation. Reductions of railway fares are offered to persons who will apply for that purpose to the Dean of the Faculty before December 13. The first general meeting of the congress will take place on January 16, and the conference will close on the 23rd of that month.

MR. C. M. IRVINE informs us that at four o'clock on the afternoon of December 4 a brilliant meteor passed over Lesmahagow, N.B., travelling true south. The altitude was about 45°. The arc through which it was visible was about 10°, and the duration of visibility nearly 3 secs. Colour, pale greenish blue. The sky was overcast with detached clouds. The passage of the meteor was slightly zigzag, deviating from a straight line by about 1° on either side.

THE second series of lectures given by the Sunday Lecture Society begins on December 10, in St. George's Hall, when Sir Benjamin W. Richardson, F.R.S., will lecture on "The Mastery of Pain." Lectures will subsequently be given by Prof. A. A. Rambaut, Royal Astronomer of Ireland; Dr. R. D. Roberts, Prof. Percy Frankland, F.R.S., Mr. C. T. Dent, Mr. Arthur W. Clayden, and Prof. R. Meldola, F.R.S.

THE following are among the lecture arrangements at the Royal Institution before Easter:—Prof. Dewar, six lectures (adapted to a juvenile auditory) on air; gaseous and liquid; Prof. Charles Stewart, nine lectures on locomotion and fixation in plants and animals; Mr. W. Martin Conway, three lectures on the past and future of mountain exploration; Prof. Max Müller, three lectures on the Vedânta philosophy; the Right Hon. Lord Rayleigh, six lectures on light with special reference to the optical discoveries of Newton. The Friday evening meetings will begin on January 19, when a discourse will be given by Prof. Dewar, on scientific uses of liquid nitrogen and air. Succeeding discourses will probably be given by Mr. A. P. Graves, Mr. T. J. Cobden-Sanderson, Prof. W. F. R. Weldon, Prof. Silvanus P. Thompson, Prof. John G. McKendrick, Dr. W. H. White, the Right Hon. Lord Rayleigh, and others.

ACCORDING to the *Times* correspondent at Cairo, Messrs. Garstin and Willcocks have inspected the four sites proposed for reservoirs in which to store water for irrigation purposes during the summer when the Nile is low, and their reports will shortly be presented. The Government will then invite three European hydraulic engineers of the highest reputation to come to Egypt and make a technical examination of the proposed schemes. This will probably be in February next. Three of these schemes are for the construction of dams across the river at either Kalabsheh, Assouan, or Silsileh; the fourth proposes to utilise the natural depression of the Wady Raian, in the province of Fayoum, by conducting into it the flood-water of the Nile.

THE London County Council some time ago decided to establish a pathological laboratory and museum in connection with the London lunatic asylums. Last week the Council accepted the plans prepared by Mr. G. T. Hine, and we understand that they will shortly be put into execution at Claybury. A competent pathologist is now to be appointed, who will be supplied with material from the Claybury and other asylums under the supervision of the London County Council. The necessity for

such a laboratory has long been felt, and although good work has been done in several asylums by enthusiastic workers, these investigations have hitherto been carried out at a great disadvantage, chiefly owing to the want of assistance on the part of the governing bodies. So great have been these difficulties that in many asylums pathological science has been totally neglected. The task of electing a pathologist will not be an easy one. It is to be hoped the choice will fall on one who has made his mark in all the various branches of neurological science; for the study of cerebral disease is so bound up with that of the spinal cord and nerves, that a knowledge of cerebral pathology must prove useless if not combined with a thorough mastery of the clinical phenomena of spinal and peripheral nervous diseases, of their lesions, and of the methods of clinical and experimental neurological investigation.

As might have been expected, the anti-vivisectionists, headed by the Lord Chief Justice of England, have memorialised the Viceroy of India and the members of the Executive and Legislative Councils. In this document the usual sentimental arguments against vivisection are stated. If with reference to the Indian Bill now under consideration for the regulation of vivisection experiments, it should be deemed advisable to legislate on the subject, the signatories suggest (*a*) that the higher animals, such as horses, asses, mules, dogs, and cats, for which special certificates are granted in England, and also monkeys, should be wholly exempted from experimentation; (*b*) that it should be made essential to keep the animals under an anæsthetic throughout the investigation; (*c*) that the use of curare should be entirely prohibited; (*d*) that it should be provided that one inspector at any rate shall be selected on account of his recognised humanity, not his scientific knowledge. The executive committee of the Society for the Protection of Animals from Vivisection have also recently transmitted to the Viceroy and the members of the Executive Council a protest against the establishment of a Pasteur Institute in India. They represent that similar institutes in Paris and elsewhere have so far failed to prevent deaths from the bites of dogs and other animals alleged to be rabid, and that 256 persons have died in spite of the preventive treatment invented by M. Pasteur. It is also remarked that the Pasteur system involves and depends upon the cultivation and perpetuation of the malady of rabies in series after series of sentient animals, to their great misery and suffering, but the benefits that mankind derives from it are naturally ignored.

During the week ending the 2nd inst. several depressions passed across these islands, causing gales on our northern coasts. In the rear of these disturbances northerly winds set in, with a great fall of temperature; on the 1st and 2nd inst. the thermometer fell to 20°, or less, in nearly all parts. In Scotland the lowest readings were between 12° and 15°. But by Sunday, the 3rd inst., the temperature rose rapidly in the north and west, and subsequently the rise extended to the southern parts of the country.

The *Meteorologische Zeitschrift* for November contains a paper on the frequency of halo phenomena, by G. Hellmann. Few text-books have dealt with this subject, and those that have done so state that lunar halos are most frequent, an error which appears to date from the time of Aristotle. Certainly the moon offers less opportunity for such phenomena. Prof. Hellmann points out that only such observatories as record hourly observations afford the necessary materials for giving a satisfactory answer to the question. He has examined various records, and especially those of the Upsala observatory, the result being that the solar phenomena exceed the lunar by about five to one, by far the most frequent halos being those of 22° radius. The halos as well as mock-suns and mock-moons show a distinct yearly period. The solar phenomena are most frequent from April to June, and the lunar phenomena are most frequent in the winter half-year, being dependent on the length of the nights. These results are supported by observations made in the United States, and also in Japan.

The *Pioneer Mail*, of November 9, contains an article on the past monsoon in India, based upon the official reports of rainfall between June 1 and October 15. These reports show a generally satisfactory state of affairs, about half the country having had excessive, and half deficient rainfall; some regions which generally receive only moderate rain had an excessive amount, while those which usually receive an excessive amount had a relatively light fall. The causes which bring about this half-yearly reversal of the winds are of especial interest, and offer a large field for study. Among the generally accepted theories, one attributes the origin of the rain-bearing current to the intense heating of the plains of Upper India, while another is that the chances of a good monsoon vary inversely with the amount of snow during the preceding winter. The writer thinks that these theories have failed in the present instance, while admitting that the distribution of heat and, under some circumstances, the snowfall exercise an influence on the monsoon. He sets up another theory, viz. that the monsoons are caused by the heated air of Asia rising up and overflowing at a great height to the southern hemisphere, where it settles down and is impelled northward by its own energy and by pressure in the rear. A reference to the "Memorandum on the Snowfall, &c." issued by the *Meteorological Reporter* on June 1 last, shows that the general forecast was to the effect that the rainfall might be deficient to a moderate extent in north-west India, and would very probably be at least normal in other parts. If any modification of the accepted theories be necessary, it will doubtless be shown by a study of the daily charts of the Indian monsoon area, to which we recently alluded, and the publication of which began with the present year. One of the special objects in preparing these charts is to elucidate the conditions which determine the advances, and variations in strength of the monsoon currents

Some interesting observations on the velocity at which crystallisation proceeds in a super-cooled substance are communicated by Mr. Moore to the current number of the *Zeitschrift für Physikalische Chemie*. The method of experiment resembles that originally used by Gernez. The substance is contained in a carefully cleaned U-tube, made of thin glass, which is immersed in a bath of liquid maintained at constant temperature, and which during an observation is kept open at both ends. When crystallisation sets in, in such a tube, the line of demarcation between solid and liquid can readily be followed by eye, and the time can easily be noted which is taken by the crystallisation to travel a definite distance down a limb of the U tube. Satisfactory observations cannot be taken when the crystallisation is rising in a limb of the tube, owing to the disturbing effects of the thermal changes attending solidification. Experiments on acetic acid showed that at any temperature the velocity is uniform, and is independent of the diameter of the tube, and observations on acetic acid, phenol, and mixtures of phenol with water and with cresol, show that the velocity increases with the amount of super-cooling, and at a diminishing rate. For phenol it is ·6 c.m. per sec. with 4°·4 super-cooling, and 2·9 c.m. with 15°·8 super-cooling. The addition of water and of cresol to phenol largely reduces both the velocity of crystallisation and the rate at which it increases with the amount of super-cooling. Several of the curves indicate a maximum velocity as the extent of super-cooling increases. Attempts to observe this maximum were rendered fruitless, however, by the spontaneous crystallisation of the substances.

Diurnal movements of the ground have been noticed at Santiago for some years, and have usually been attributed to the

action of heat upon the Santa Lucia mountain. According to *La Nature*, the observatory has recently been removed to a plain at the south of the city, and Dr. Obrecht, the director, has investigated the movements. It appears from his observations that from noon until nine o'clock in the evening, the ground to the north-east is raised, and then gradually descends until seven o'clock on the following morning. These curious variations sometimes attain an amplitude of 3″ or 4″. There is also evidence that from July to September the ground to the north-east is continuously raised, while from September to November, the part to the east of the observatory is continuously elevated. The total amplitude of elevation is said to be about 35″.

Mr. A. Sigson, a professional photographer at Rybinsk, contributes an account of his method of obtaining photographs of snowflakes to the *Journal of the Russian Physico-Chemical Society*. He used a Zeiss microscope provided with an aplanatic lens and a long focus camera. This was placed near an attic window at a strong inclination to the horizon. The flakes were received on some rough cloth and transferred to a small net of cocoon fibres stuck on a card perforated in the middle. This card was placed on the stage of the microscope, and the illumination was so arranged that half the field was uniformly illuminated, and the other half shaded off. For an enlargement of fifteen times the exposure lasted two to five seconds, with plates supplied by M. Lumière. To avoid the melting of the flakes by the breath of the operator, the latter is obliged to breathe through a pipe bent backwards during the adjustment of the apparatus.

In *Bulletin* No. 8 of the Geological and Natural History Survey of Minnesota, Dr. Andrew C. Lawson publishes two papers of great importance for the systematic grouping of volcanic rocks in North America. The first paper is on the "Anorthosytes of the Minnesota Coast of Lake Superior," and is prefaced by a long note, written by Prof. Winchell, on "The Norian of the North-West." In this note Prof. Winchell gives up many of his previously-formed ideas regarding the Minnesota rocks, in favour of the conclusions now obtained by Dr. Lawson. There occurs on the Minnesota coasts a rock almost wholly composed of a plagioclase felspar which had been included by Profs. Winchell and Irving in the Keweenian or Cupriferous series of volcanic lavas and sheets. For this rock, Dr. Lawson accepts the name of "Anorthosyte," given by Prof. Adams to similar rocks in the Norian series of Quebec; and he proves conclusively that it is a Plutonic formation, solidified under deep-seated conditions, and exposed later during the long period of pre-Palæozoic erosion. On its eroded surface the volcanic lavas of the Keweenian series were poured out, no rocks belonging to the Animikie series being present in this area. The thickness of the Keweenian series had been estimated by Prof. Irving at 20,000 feet. Dr. Lawson is of opinion that the series is comparatively thin, ranging from zero to a maximum of a few hundred feet. Special interest attaches to the hummocky—*roches moutonées*—aspect of the old surfaces of the Anorthosyte rock at Beaver Bay, Carlton Peak, &c., as this is such a marked feature of the ancient erosion planes of Archæan rocks in North America. Dr. Lawson compares the Anorthosytes of Minnesota with the Norian series of irruptive plagioclase rocks invading Archæan gneisses in Quebec, but until there is sufficient evidence in favour of this correlation, he suggests that a local name of "Carltonian" be given to the Minnesota Anorthosytes.

The second paper in the same *Bulletin*, by Dr. Lawson, is entitled "The Laccolitic Sills of the North-West Coast of Lake Superior." Extensive trap-sheets are in this region associated with the Animikie and Nipigon groups of sedimentary rocks, and have up to this time been described as contemporaneous flows. Mr. Ingall had observed the intrusive nature of some of these so-called flows, but drew no farther conclusions. Dr. Lawson now advances the view that "there are no contemporaneous volcanic rocks in the Animikie group, and that the trap-sheets are all intrusive in their origin, and are of the nature of laccolitic sills." He supports this view by weighty evidence, such as the simplicity of the trap-sheets, their regularity and persistence over wide areas, the passage of thick sheets from the Animikie series into the higher horizons of Keweenian strata, the absence of pyroclastic rocks, the alteration of the rocks above and below the intruded sheets, and the direct continuity of the "trap-sheets" with dykes of the same intrusive rock. The "trap-sheets" occur as laccolitic sills both in the Animikie and Keweenian series, and are therefore later than these. Dr. Lawson thinks they may belong to the great series of trap-rocks intruded in the Silurian rocks of Quebec, but calls them for the present "Logan Sills," in honour of the late Sir William E. Logan.

It is well known that electric currents may be produced by heating a single metal, if there be any variation in temper, or if the distribution of heat be very irregular, and the changes of temperature abrupt. Mr. W. H. Steele has made some experiments on these effects, in the Physical Laboratory of Melbourne University (*Science*, No. 562). A sensitive galvonometer put in circuit with a piece of iron wire showed a current when the wire was simply warmed with the fingers. This was the only metal which gave a current when at a temperature below 100° C. Altogether twelve different metals and four alloys were examined, and the effect noticed in each of them. In order to raise the wires to a high temperature without fusing them, they were passed through clay tubes (stems of tobacco-pipes), and, in the case of metals having low melting-points, the tube was completely filled with the metal. The highest electromotive force obtained from iron was 0·002 volt; 0·3 volt was observed with six different metals—lead, copper, gold, tin, zinc, and antimony; while with others, *e.g.* silver and aluminium, the effect was exceedingly small. In the case of lead, the effect showed no sign of ceasing after the metal had been heated for half a day. Gold gave the highest effect, as much as half a volt being observed. Mr. Steele remarks that these phenomena are generally quite sufficient to mask the ordinary thermo-electric effect at a red heat, and that thermo-electric tables are consequently not trustworthy for high temperatures.

The current number of the *Comptes Rendus* contains a note, by M. Ch. André, on the variation of the electric state of the high regions of the atmosphere in fine weather. During a previous attempt to investigate this point, the author unfortunately met with an accident which has prevented him personally making any more observations; the measurements contained in this note have, however, been made under his direction. At opposite corners of the car of the balloon were fixed two cylindrical reservoirs, filled with distilled water, and insulated on plates of sulphur. To the base of each of these vessels an india-rubber tube, about 20 metres long, was attached, each tube having a small jet at its end. When the balloon had come to rest at any desired height, the difference of potential existing between two points, at a known vertical distance, was determined by means of an electrometer (Exner's pattern) connected metallically with the water reservoir. This difference of potential, the distance being kept constant, gave a measure of the strength of the electrical field. As a result of two series of observations, the author considers that in fine weather the strength of the electrical field does not increase with the altitude, but is the same at a given instant at any point along the same vertical.

In a paper communicated to the Reale Accademia delle Scienze, Torino, Signor Garbasso gives an account of his experiments on the reflection of electrical waves. The author allows the waves given out by a Hertz oscillator to fall upon a mirror consisting of a wooden plank 175 c.m. long and 125 c.m. broad, over which were stretched a large number (168) of parallel rectilinear resonators. These resonators were without spark-gaps, and consisted of wires 20 c.m. long with metal discs, 3·8 c.m. in diameter, fixed at either end. When another resonator, having a spark-gap, is placed so that the radiation reflected from this mirror falls upon it, bright sparks are produced, as has been shown by Trouton and others, when its length is parallel to the wires on the reflector, while no sparks are produced when it is at right angles to these wires. What seems curious, however, is that the radiation reflected, although it has such a large wave-length compared with the dimensions of the mirror, is not scattered but is regularly reflected.

In No. 5, vol. xii. of the *Zeitschrift für Physikalische Chemie*, Mr. Harry C. Jones gives an account of an additional series of observations on the freezing-points of dilute aqueous solutions. The most dilute solutions employed were in general about ·001—normal. Of the inorganic substances examined ammonia exhibited the most striking behaviour. Although the bases potash and soda like hydrochloric and nitric acid seem to be almost entirely dissociated into ions, ammonia is only dissociated to the extent of some twenty per cent. Phosphoric acid apparently dissociates into the two ions H and H_2PO_4, aud in the most dilute solutions is less dissociated than sulphuric acid, which in turn is less dissociated than the monobasic acids. The extent of the dissociation thus obtained agreed, in the main, with that deduced from Kohlrausch's observations on the electric conductivity of the solutions. The organic substances examined gave quite unexpected results. Cane-sugar, dextrose, urea, phenol, and ethyl and propyl alcohols, which, according to the new theory, cannot undergo electrolytic dissociation, behaved in all cases in the most dilute solutions as if they were really dissociated, and gave molecular lowerings of the freezing-point which were much higher than the calculated value. Indeed, if one supposes for the moment that cane-sugar can dissociate into two ions, the observations on the freezing-point of its aqueous solutions, when treated as in the case of an electrolyte, would indicate that twenty-seven per cent. of the sugar is dissociated, or an amount greater than that found for ammonia. With rise in concentration the molecular lowering for all the organic substances diminishes, in some cases reaching a minimum and then increasing, or, as in the case of urea and the two alcohols, remaining constant. This constant minimum value of the molecular lowering agrees closely with the theoretical number. The explanation of these remarkable results from the standpoint of the new theory will be awaited with interest.

The marked increase in the vitality of the cholera bacillus in artificial culture media induced by adding larger than usual proportions of salt to the latter, was drawn attention to in these notes on August 24, in connection with the saline condition of the river Elbe at the intake of the Hamburg water-works during the great cholera epidemic. In a subsequent note, on September 28, it was pointed out how this property of the cholera organism had been taken advantage of by Koch and others in devising methods for the separate identification of this vibrio in water in the presence of other harmless saprophytic bacteria. Of extreme interest, therefore, are the experiments of Dr. M. N. Gamaleia, contained in a short paper, "Du cholèra virulent et épidémique," contributed to the *Comptes Rendus*, No. 5, 1893, p. 285. This investigator states that he was able to increase the *virulence* of the cholera organism by cultivating it in media containing from 3, 4, up to 5 per cent. of common salt. Nor were these results confined to one particular cultivation of the cholera bacillus, but were also derived with cholera cultures obtained from numerous different sources. On inoculating these salt-cultures of cholera vibrios into pigeons and guinea-pigs, symptoms of septicæmia developed, invading the blood and all the tissues. If one drop of the blood of these infected animals was taken and inoculated into others, the malady was transmitted. These observations support the theory that the unusual saline condition of the Elbe may have assisted in supplying the conditions which so greatly favoured the vitality and virulence of the cholera bacillus during the Hamburg epidemic.

The last two numbers of the *Botanische Zeitung*, published on November 1, are devoted to a memoir by E. Crato, "Morphologische und mikrochemische Untersuchungen ueber die Physoden." This memoir is stated to be an "Arbeit" carried on under the direct guidance of Prof. Dr. Reinke, at the University of Kiel, and the following is from the summary given by the author :—There lies at the basis of the vegetable cell a system of delicate lamellæ, arranged in such a way as to form a foam-like mass (Lamellensystem, Gerüstsubstanz). In those plants where the point has been carefully investigated, these lamellæ do not give the ordinary proteid reactions. The spaces enclosed by the lamellæ contain a clear, watery, slightly refractive fluid (Kammerflüssigkeit), whereto belong both cell-sap as well as enchylema. In these lamellæ there glide about, apparently at will, minute, refractive, bladder-like formations (physodes, to which the greater part of the microsomes belong), swelling out the lamellæ where they occur. These physodes certainly form readily transportable vehicles of chemical substances for the plant. In the brown Algæ these physodes contain substances similar to phenol. In all the Algæ which were investigated, the Laminaria excepted (their investigation is not complete), phloroglucin was found. Further, it would appear that these phenol-like substances are used up for the formation of the lamellar substance (plasma, &c).

Major J. W. Powell's eighth annual report, as Director of the U.S. Bureau of Ethnology, is a splendid addition to ethnological literature. In the first part of the volume the plans and operations of the Bureau are described, a brief account being given of the many investigations carried on during the fiscal year 1886–87 by the twenty-five assistants. The contributions contained in the volume are : "A Study of Pueblo Architecture, Tusayan and Cibola," by Mr. Victor Mindeleff, and "Ceremonial of Hasjelti Dailjis and Mythical Sand Painting of the Navajo Indians," by Mr. James Stevenson, this being his last official work before his death in 1888. In these papers "the prehistoric archæology of the Pueblos in the special department of architecture is the most prominent single subject presented and discussed ; but the papers also include studies of the history, mythology, and sociology of that people, as well as of their neighbours and hereditary enemies, the Navajo." All these correlated studies are set forth in detail, and, are profusely illustrated. Mr. Mindeleff's study relates to the ruins and inhabited towns found over a large territory in the interior south-western parts of the United States. His research leads him to conclude that there is no need for the hypothesis of an extinct race with dense population and high civilisation to account for the conditions actually existing in North America before the European discovery. Mr. Stevenson's paper is most interesting, and it has the advantage of being a statement of facts actually witnessed by the deceased author. Translations of six of the Navajo myths are also presented, some of which elucidate parts of the ceremony forming the main title of his paper. The whole work has been excellently done, and our only regret is that there should have been a delay of six years in its publication.

DURING the summers of 1891 and 1892 Mr. W. P. Hay took the opportunity, while visiting the caves of Southern Indiana, to observe the habits of the blind crayfish, *Cambarus pellucidus*. In some of the caverns, as at Shiloh Cave, the crayfish were extremely abundant. When observed in an undisturbed state, they were found resting quietly in some shallow part of the underground streams on the clay banks. They lay with all their legs extended, and their long antennæ gently waving about to and fro. They were easier caught by the hand suddenly seizing them than with a net. Noise did not seem to affect them. When first taken out of the water they were of a translucent pinkish white colour, with the alimentary track showing through as a blue body, but they soon lost these hues. The variation in the general spininess is very great. As a rule, the farther north the specimens were taken the smoother they were. At Mayfield's Cave, in Monroe County, a variety was found entirely without spines; this is described and figured as a sub-species. (Proc. U.S. Nat. Museum, No. 935, 1893.)

IN Wundt, *Philosophische Studien*, ix. Bd., 1 Heft., Herr Bruno Kämpfe brings together all the values of the integral for the probable error, *i.e.*

$$\phi(\gamma) = \frac{2}{\sqrt{\pi}} \cdot \int_0^\gamma e^{-t^2} dt,$$

which gives the whole number of errors, both positive and negative, whose numerical magnitude falls between the given limits. The number of errors between any two given limits will be found by taking the difference between the tabular numbers corresponding to these limits. Since the total number of errors is taken as unity in the table, the required number of errors in any particular case is to be found by multiplying the tabular numbers of the actual number of observations. Thus, to take an example, if there were 1000 observations, and we wish to employ the limits 0·0 and 0·5, then looking in the column giving the values of γ, we find against them the numbers 0·0000 and 0·5205, which when subtracted from one another, and multiplied by 1000 give 520·5 or 520 errors. If the limits had been 1·5 and 2·0, then we should have found the corresponding values 0·9661 and 0·9953, which subtracted give 0·0292, and multiplied by 1000 give 29, *i.e.* 29 errors that lie between these limits out of 1000 observations. This table is published also as a *separatabdruck* by Wilhelm Engelmann, Leipzig, which is in a more useful form for computation. The values of γ can be read directly to three places of decimals.

WE have received a report of the meteorological observations made during 1892 at the Royal Alfred Observatory, Mauritius.

THE new issue of Mr. Edward Stanford's compendium of geography and travel includes a revised and partly rewritten edition of "Australasia." Under this title Dr. A. R. Wallace's excellent description of Australia and New Zealand has been published, and a second volume, embracing Malaysia and the Pacific Archipelagoes, by Dr. F. H. H. Guillemard, is in preparation.

MM. J. B. BAILLIÈRE ET FILS have added to their library of contemporary science a volume entitled "Pêches et Chasses Zoologiques," by the Marquis of Folin. The book is well illustrated, and, though much of the matter it contains is only of local interest, a large portion will be read with profit by students of natural history.

IT is very doubtful whether any useful purpose is served by the issue, from Mr. Edward Stanford's, of the series of maps edited by Captain A. Staggemeier, of Copenhagen. The maps show very little except the configuration of the land surfaces, the editor's idea being that they will be of service to physical geographers for placing observed facts of natural history, meteorology, &c., in their proper geographical position. There are five maps in the portfolio before us, two showing the Polar regions down to 30°, and three the zone between 45° of North and South latitude, on Mercator's projection; hence the zones between latitudes 30° and 45° are represented on both projections. It is intended to issue other maps on a larger scale, the whole series to comprise twenty-five plates, which will be published in six parts.

IT is encouraging to learn, from the forty-first annual repor of the working of the Manchester Public Free Libraries, tha during the year 1892–93, 77,878 volumes dealing with science and art were issued from the reference library, and 67,456 were referred to in the reading-room. The total number of books issued to borrowers by the nine branch libraries was 872,655, of which 45,526 are classified under science and art. Of the 100,123 volumes consulted in the reading-rooms of the branch libraries, 7869 were on science and art subjects. The record is a good one; but if the committee were to classify science separately from art, we should be better able to estimate from the figures the growth of interest in natural knowledge.

DR. ARTHUR GAMGEE has just completed the second volume of his text-book on the Physiological Chemistry of the Animal Body, upon which he has been engaged for some years. Like the first volume, it constitutes an independent and complete treatise, dealing with the physiological chemistry of the digestive processes. It has been the author's aim to give the reader a very full and, so far as possible, independent account of the state of knowledge on the subjects discussed. Messrs. Macmillan and Co. will publish the volume immediately.

MESSRS. MACMILLAN AND CO. are also about to publish a revised and enlarged edition of "Elementary Lessons in Steam Machinery and the Marine Steam Engine," by Messrs. Langmaid and Gaisford, Instructors on H.M.S. *Britannia*. It will be followed by other works constituting a Britannia Science Series. Among those already in hand may be mentioned "Physics for School Use," by Mr. F. R. Barrett, Mr. A. E. Gibson, Rev. J. C. P. Aldous, and others; a "Physics Note-Book," by Messrs. Gibson and Aldous; "Trigonometry for Practical Men," by Mr. W. W. Lane; and "Geometrical Drawing, Perspective, and Mechanical Drawing," by Mr. J. H. Spanton.

THE additions to the Zoological Society's Gardens during the past week include a Mozambique Monkey (*Cercopithecus pygerythrus*, ♂) a Sykes's Monkey (*Cercopithecus albigularis*, ♂) a Bell's Cinixys (*Cinixys belliana*) from East Africa, presented by Mr. T. E. C. Remington; a Red Tiger Cat (*Felis chrysothrix*) from the Gold Coast, West Africa, presented by Mr. William Adams; a Common Otter (*Lutra vulgaris*) from Yorkshire, presented by Mr. C. B. C. de Wit; a Herring Gull (*Larus argentatus*) British, presented by Mr. J. G. Goodchild; a Northern Mocking Bird (*Mimus polyglottus*) from North America, presented by Miss Dorothy Williams; a Viperine Snake (*Tropidonotus viperinus*) European, presented by Miss Ffennell; five Barbary Partridges (*Caccabis petrosa*) from North Africa, deposited.

OUR ASTRONOMICAL COLUMN.

THE VARIATION OF LATITUDE.—In the *Astronomical Journal*, No. 19 (November 14), Prof. S. C. Chandler gives the eighth of the important series of articles that he has been contributing on the variation of latitude. The special part of the subject which is referred to deals with the direction of the rotation of the pole and is accompanied by an explicit demonstration which includes all the data bearing upon it. Owing to the insufficient extent of series of observations in widely different longitudes to furnish independent values of the constants

for both terms of the variation, Prof. Chandler has thought well to combine short series made in nearly the same longitudes, and so deduced fourteen determinations of the numerical equations for the latitude variation. Reducing the values so obtained to a common epoch, he found that the values of the observed Julian date when the latitude would be a minimum, or when the pole of figure would pass the meridian of the respective stations by virtue of the fourteen months' revolution alone, and of the sun's longitude on the observed date when the same phase would occur by virtue of the annual term alone, both decreased from Pulkowa *towards* Madison showing that the direction of the rotations in both the elements was from west to east. In the latter part of the article Prof. Chandler refers not only to our knowledge of the general law of latitude variation, but to the accuracy of the necessary constants which afford us a means of predicting the immediate future course. The minimum of the curve of April, 1893, will be followed by an interval of nearly two years, and will be marked by very slight fluctuations, so that from the maximum of October, 1893, to that of August, 1895, or from minimum April, 1893, to that near the beginning of 1895, "there will apparently be but a single decidedly marked period of, say 20–22 months," the total range amounting to 0"·10 as against 0"·56 which prevailed in 1889 and 1892. In May, 1896, the same dimensions as in 1889 will be again attained, and the variation from that time forward to 1898 it will be in full play with the range of 0"·5 or 0"·6, a period of nearly 390 days which prevailed between 1889 and 1892. In § 2 of the article Prof. Chandler adds a few words as to the reality of these movements of the earth's axis as against the motions being "merely misinterpretations of the observed phenomena" or an illusory effect of instrumental error due to the influence of temperature. Those of our readers who are still sceptical on the subject will learn that the observed law of latitude variation includes two terms, one with a period of fourteen months, and another with twelve months, making the phases come in very different relations to conditions of temperature dependent on season, an argument greatly against that brought forward by temperature-variation believers.

METEOR SHOWER FOR DECEMBER.—No news is yet to hand with regard to the Biela meteors, but we hope soon to receive accounts of the display which will give us some idea of the quantity and also of the date of reaching their maximum. The following meteor radiant-points are given by Mr. Denning for the ensuing month, that for the 10th lying approximately close to ρ Gemini in a prolongation of β and ρ Gemini, and being defined as a "most brilliant shower."

Date.		Radiant. α	δ		Meteors.
Dec. 8	...	145	+ 7	...	Swift; streaks
8	...	208	+ 71	...	Rather swift
10	...	108	+ 33	...	Swift; short
24	...	218	+ 36	...	Swift; streaks
25	...	98	+ 31	...	Very slow

REFRACTION TABLES.—We have received a small pamphlet extracted from the *Mitheilungen aus der Deutschen Schutzgebieten*, Bd. vi., Heft 4, containing refraction tables computed by Dr. L. Ambronn, of the Göttingen observatory. These tables are not intended for such accurate values as are required in observatories with fixed instruments, but are intended to be used by those, who having made astronomical observations, wish to compute them on the spot, using approximate formulæ. Travellers, especially, will find these tables very useful for wide ranges, both as regards temperature and barometer arguments. The tables are based on Bessel's refraction-table formula, and by slightly combining the first two terms, which is no other than the mean refraction, and eliminating the term *log* T by reducing the height of the barometer to 0°C becomes, employing the usual notation:

$$\log \text{refraction} = \log \alpha \tan z + A \log B_0 + \lambda \log \gamma$$

or

$$\text{refraction} = \alpha \tan z \times B_0^A \times \gamma^\lambda \quad . \quad . \quad . \quad . \quad (1)$$

To make the correction for the mean refraction additive, the expression can be put in the form:

$$\text{refraction} = [\alpha \tan z + \alpha \tan z (\gamma^\lambda - 1)] B_0^A$$

Table II. gives the expression for the second term in the brackets using the mean refraction ($\alpha \tan z$) and the air temperature (γ) as arguments. For the barometer correction, if $\alpha \tan z$ represent the mean refraction corrected for temperature then in equation (1) we may omit γ and write

$$\text{refraction} = (\alpha \tan z) \times B_0^A$$
$$\text{or, refraction } (\alpha \tan z) \times (\alpha \tan z) [B_0^A - 1]$$

The second term is taken direct from Table III. using the the mean refraction (corrected for temperature) and the height of the barometer as arguments.

To obtain the true refraction then, one simply (1) finds the mean refraction for the given zenith distance; (2) adds then the correction for temperature, and with this corrected mean refraction as argument; (3) adds the corresponding correction for the height of the barometer. Accuracy up to less than half a second of arc can be obtained.

GEOGRAPHICAL NOTES.

THE friends of the late Emin Pasha, at the suggestion of Dr. Schweinfurth, have resolved to collect subscriptions for a memorial to commemorate his long labours in Africa as a naturalist, traveller, and administrator. There must be many in this country anxious to have a share in such a tribute, and we shall shortly be able to intimate where subscriptions should be sent. The present proposal is to erect a monument in the Silesian town of Neisse.

BY the death of Mr. A. L. Bruce, at Edinburgh last week, the cause of geography and civilisation in Africa has lost a wealthy and judicious promoter. Mr. Bruce, who married as his second wife a daughter of Dr. Livingstone, was a director and one of the founders of the Imperial British East Africa Company. He was a devoted friend and warm supporter of Mr. H. M. Stanley, and took a leading position in organising and supporting the Emin Relief Expedition. Mr. Bruce was the originator of the Royal Scottish Geographical Society, of which he acted as treasurer, and in the prosperity of which he took the keenest interest to the last.

GUILIO GRABLOVITZ has published as a pamphlet a paper on tidal phenomena in the Mediterranean, read at the Italian Geographical Congress, and entitled "Sulla Osservazioni Mareografiche in Italia e specialmente su quelle fatte ad Ischia." The work done with recording mareographs is of considerable importance and several diagrams are given showing the tidal range and its fluctuations. The mean rise of the water was 11 centimetres at San Remo, 24 at Genoa, 12 in the North of Sardinia, from 15 to 22 along the west coast of Italy as far as Ischia, 30 in the Lipari Islands, but only from 2 to 13 round Sicily. In the Adriatic the range increased from 9 centimetres at Brindisi to 48 at Venice, which was the only station showing a range greater than one foot. The curves are recorded on a large scale, the ripples of the calm water in which the mareograph worked bearing a comparatively large ratio to the total tidal amplitude.

MONT ISERAN, in the eastern Alps, is, or rather was, one of the most remarkable mountains on the map of Europe, where it flourished long, although without any physical representative on the mountain-range itself. M. Henri Ferrand, in an entertaining little *brochure* relates its story, showing how it had come to be an accepted belief amongst cartographers that the river Isère had its source in a Mont Iseran. The mountain was fixed in latitude, longitude, and altitude by an Italian surveyor in 1809; but in the fifties, when Alpine climbing became fashionable, the discovery was made by climbers that no one in the neighbourhood could point out Mont Iseran. There was a col of that name, but no peak. An exhaustive French survey conclusively proved that the summit so long honoured on all maps had no real existence, and M. Ferrand tells the whole amusing history remarkably well as a lesson of the value of mountain-climbing, even to scientific topography.

THE telegraphic cable opened last month from Zanzibar to Mauritius and Seychelles is an important link in the cable network which is gradually encompassing the globe.

THE ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

THE anniversary meeting of the Royal Society was held in the apartments of the Society at Burlington House, on St. Andrew's Day, November 30. The auditors of the

treasurer's accounts having presented their report, the secretary read the list of Fellows elected and deceased since the last anniversary. The Society has lost eleven fellows on the home list, and two foreign members, as follows :—

Henry Tibbats Stainton, December 2, 1892, aged 70.
Sir Richard Owen, December 18, 1892, aged 89.
Dr. James Jago, January 18, 1893, aged 77.
Henry Francis Blanford, January 23, 1893, aged 58.
Thomas William Fletcher, February 1, 1893, aged 84.
Edward Walker, March 2, 1893, aged 73.
Alphonse de Candolle, March 28, 1893, aged 87.
Henry Edward Stanley, Earl of Derby, April 21, 1893, aged 67.
Ernest Edward Kummer, May 14, 1893, aged 84.
Rev. Charles Pritchard, May 28, 1893, aged 85.
Dr. John Rae, July 22, 1893, aged 80.
Thomas Hawksley, September 23, 1893, aged 86.
Sir Andrew Clark, Bart., November 6, 1893, aged 67.

The Society next proceeded to elect the officers and council for the ensuing year. A list of those selected for election was given in NATURE, November 9.

Lord Kelvin, the President, then delivered his address. After briefly referring to the work of the Standing Committees, he continued as follows :—

Not the least important of the scientific events of the year is the publication, in the original German and in an English translation by Prof. D. E. Jones, of a collection of Hertz's papers describing the researches by which he was led up to the experimental demonstration of magnetic waves. For this work the Rumford Medal of the Royal Society was delivered to Prof. Hertz three years ago by my predecessor, Sir George Stokes. To fully appreciate the book now given to the world, we must carry our minds back to the early days of the Royal Society, when Newton's ideas regarding the forces which he saw to be implied in Kepler's laws of the motions of the planets and of the moon were frequent subjects of discussion at its regular meetings, and at perhaps even more important non-official conferences among its Fellows.

In 1684 the senior secretary of the Royal Society, Dr. Halley, went to Cambridge to consult Mr. Newton on the subject of the production of the elliptic motion of the planets by a central force,[1] and on December 10 of that year he announced to the Royal Society that he "had seen Mr. Newton's book, 'De Motu Corporum.'" Some time later, Halley was requested to "remind Mr. Newton of his promise to enter an account of his discoveries in the register of the Society," with the result that the great work "Philosophiæ Naturalis Principia Mathematica" was dedicated to the Royal Society, was actually presented in manuscript, and was communicated at an ordinary meeting of the Society on April 28, 1686, by Dr. Vincent. In acknowledgment, it was ordered "that a letter of thanks be written to Mr. Newton, and that the printing of his book be referred to the consideration of the council; and that in the meantime the book be put into the hands of Mr. Halley, to make a report thereof to the council." On May 19 following, the Society resolved that "Mr. Newton's 'Philosophiæ Naturalis Principia Mathematica' be printed forthwith in quarto, in a fair letter; and that a letter be written to him to signify the Society's resolution, and to desire his opinion as to the volume, cuts, &c." An exceedingly interesting letter was accordingly written to Newton by Halley, dated London, May 22, 1686, which we find printed in full in Weld's "History of the Royal Society" (vol. i. pp. 308-309). But the council knew more than the Royal Society at large of its power to do what it wished to do. Biology was much to the front then, as now, and the publication of Willughby's book, "De Historia Piscium," had exhausted the Society's finances to such an extent that the salaries even of its officers were in arrears. Accordingly, at the council meeting of June 2, it was ordered that "Mr. Newton's book be printed, and that Mr. Halley undertake the business of looking after it, and printing it at his own charge, which he engaged to do."

It seems that at that time the office of treasurer must have been in abeyance; but with such a senior secretary as Dr. Halley there was no need for a treasurer.

Halley, having accepted copies of Willughby's book, which had been offered to him in lieu of payment of arrears of salary[1] due to him, cheerfully undertook the printing of the "Principia" at his own expense, and entered instantly on the duty of editing it with admirable zeal and energy, involving, as it did, expostulations, arguments, and entreaties to Newton not to cut out large parts of the work which he wished to suppress[2] as being too slight and popular, and as being possibly liable to provoke questions of priority. It was well said by Rigaud, in his "Essay on the first publication of the Principia," that "under the circumstances it is hardly possible to form a sufficient estimate of the immense obligation which the world owes in this respect to Halley, without whose great zeal, able management, unwearied perseverance, scientific attainments, and disinterested generosity the 'Principia' might never have been published."[3] Those who know how much worse than "law's delays" are the troubles, cares, and labour involved in bringing through the press a book on any scientific subject at the present day will admire Halley's success in getting the "Principia" published within about a year after the task was committed to him by the Royal Society two hundred years ago.

When Newton's theory of universal gravitation was thus made known to the world Descartes' *Vortices*, an invention supposed to be a considerable improvement on the older invention of crystal cycles and epi-cycles from which it was evolved, was generally accepted, and seems to have been regarded as quite satisfactory by nearly all the philosophers of the day.

The idea that the sun pulls Jupiter, and Jupiter pulls back against the sun with equal force, and that the sun, earth, moon, and planets all act on one another with mutual attractions, seemed to violate the supposed philosophic principle that matter cannot act where it is not. Descartes' doctrine died hard among the mathematicians and philosophers of continental Europe; and for the first quarter of last century belief in universal gravitation was an insularity of our countrymen.

Voltaire, during a visit which he made to England in 1727, wrote: "A Frenchman who arrives in London finds a great alteration in philosophy, as in other things. He left the world full; he finds it empty. At Paris you see the universe composed of vortices of subtle matter; at London we see nothing of the kind. With you it is the pressure of the moon which causes the tides of the sea; in England it is the sea which gravitates towards the moon. . . . You will observe also that the sun, which in France has nothing to do with the business, here comes in for a quarter of it. Among you Cartesians all is done by impulsion: with the Newtonians it is done by an attraction of which we know the cause no better"[4] Indeed, the Newtonian opinions had scarcely any disciples in France till Voltaire asserted their claims on his return from England in 1728. Till then, as he himself says, there were not twenty Newtonians out of England.[5]

In the second quarter of the century sentiment and opinion in France, Germany, Switzerland, and Italy experienced a great change. "The mathematical prize questions proposed by the French Academy naturally brought the two sets of opinions into conflict." A Cartesian memoir of John Bernoulli was the one which gained the prize in 1730. It not infrequently happened that the Academy, as if desirous to show its impartiality,

[1] Whewell's "History of the Inductive Sciences," vol. ii. p. 77.

[1] It is recorded in the Minutes of Council that the arrears of salary due to Hooke and Halley were resolved to be paid by copies of Willughby's work. Halley appears to have assented to this unusual proposition, but Hooke wisely "desired six months' time to consider of the acceptance of such payment."

The publication of the "Historia Piscium," in an edition of 500 copies, cost the Society £400. It is worthy of remark, as illustrative of the small sale which scientific books met with in England at this period, that, a considerable time after the publication of Willughby's work, Halley was ordered by the Council to endeavour to effect a sale of several copies with a bookseller at Amsterdam, as appears in a letter from Halley requesting Boyle, then at Rotterdam, to do all in his power to give publicity to the book. When the Society resolved on Halley's undertaking to measure a degree of the earth, it was voted that "he be given £50 or fifty 'Books of Fishes.'" (Weld's "History of the Royal Society," vol. i. p. 310.)

[2] "The third [book] I now design to suppress. Philosophy is such an impertinently litigious lady that a man had as good be engaged in lawsuits as have to do with her. I found it so formerly, and now I am no sooner come near her again but she gives me warning. The first two books without the third will not so well bear the title of 'Philosophiæ Naturalis Principia Mathematica,' and therefore I have altered it to this, 'De Motu Corporum Libri duo'; but, upon second thoughts, I retain the former title. 'Twill help the sale of the book, which I ought not to diminish now 'tis yours." (*Ibid.*, p. 311.)

[3] *Ibid.*, p. 310.

[4] Whewell's "History of the Inductive Sciences," vol. ii. pp. 202-203.

[5] *Ibid.*, vol. ii. p. 201.

divided the prize between Cartesians and Newtonians. Thus, in 1734, the question being the cause of the inclination of the orbits of the planets, the prize was shared between John Bernoulli, whose memoir was founded on the system of vortices, and his son Daniel, who was a Newtonian. The last act of homage of this kind to the Cartesian system was performed in 1740, when the prize on the question of the tides was distributed between Daniel Bernoulli, Euler, Maclaurin, and Cavallieri; the last of whom had tried to amend and patch up the Cartesian hypothesis on this subject.[1]

On February 4, 1744, Daniel Bernoulli wrote as follows to Euler: "Uebrigens glaube ich, dass der Aether sowohl *gravis versus solem*, als die Luft versus terram sey, und kann Ihnen night bergen, dass ich über diese Puncte ein völliger Newtonianer bin, vnd verwundere ich mich, dass sie den Principiis Cartesianis so lang adhäriren; es möchte wohl einige Passion vielleicht mit unterlaufen. Hat Gott können eine *animam*, deren Natur uns unbegreiflich ist, erchaffen, so hat er auch können eine attractionem universalem materiae imprimiren, wen gleich solche attractio *supra captum* ist, da hingegen die Principia Cartesiana allzeit *contra captum* etwas involviren."

Here the writer, expressing wonder that Euler had so long adhered to the Cartesian principles, declares himself a thorough-going Newtonian, not merely in respect to gravitation *versus* vortices, but in believing that matter may have been created simply with the law of universal attraction without the aid of any gravific medium or mechanism. But in this he was more Newtonian than Newton himself.

Indeed Newton was not a Newtonian, according to Daniel Bernoulli's idea of Newtonianism, for in his letter to Bentley to date February 25, 1792,[2] he wrote: "That gravity should be innate, inherent, and essential to matter, so that one body may act upon another at a distance through a vacuum without the mediation of anything else, by and through which their action and force may be conveyed from one to another, is to me so great an absurdity that I believe no man who has in philosophical matters a competent faculty of thinking can ever fall into it." Thus Newton, in giving out his great law, did not abandon the idea that matter cannot act where it is not. In respect, however, of merely philosophic thought, we must feel that Daniel Bernoulli was right; we can conceive the sun attracting Jupiter, and Jupiter attracting the sun, without any intermediate medium, if they are ordered to do so. But the question remains, Are they so ordered? Nevertheless, I believe all, or nearly all, his scientific contemporaries agreed with Daniel Bernoulli in answering this question affirmatively. Very soon after the middle of the eighteenth century Father Boscovich[3] gave his brilliant doctrine (if infinitely improbable theory) that elastic rigidity of solids, the elasticity of compressible liquids and gases, the attractions of chemical affinity and cohesion, the forces of electricity and magnetism—in short, all the properties of matter except heat, which he attributed to a sulphurous fermenting essence—are to be explained by mutual attractions and repulsions, varying solely with distances, between mathematical points endowed also, each of them, with inertia. Before the end of the eighteenth century the idea of action-at-a-distance through absolute vacuum had become so firmly established, and Boscovich's theory so unqualifiedly accepted as a reality, that the idea of gravitational force or electric force or magnetic force being propagated through and by a medium seemed as wild to the naturalists and mathematicians of 100 years ago as action-at-a-distance had seemed to Newton and his contemporaries 100 years earlier. But a retrogression from the eighteenth century school of science set in early in the nineteenth century.

Faraday, with his curved lines of electric force, and his dielectric efficiency of air and of liquid and solid insulators, resuscitated the idea of a medium through which, and not only through which but *by* which, forces of attraction or repulsion, seemingly acting at a distance, are transmitted. The long struggle of the first half of the eighteenth century was not merely on the question of a medium to serve for gravific mechanism, but on the correctness of the Newtonian law of gravitation as a matter of fact however explained. The corresponding controversy in the nineteenth century was very short, and it soon became obvious that Faraday's idea of the transmission of electric

force by a medium not only did not violate Coulomb's law of relation between force and distance, but that, if real, it must give a thorough explanation of that law.[1] Nevertheless, after Faraday's discovery[2] of the different specific inductive capacities of different insulators, twenty years passed before it was generally accepted in continental Europe. But before his death, in 1867, he had succeeded in inspiring the rising generation of the scientific world with something approaching to faith that electric force is transmitted by a medium called ether, of which, as had been believed by the whole scientific world for forty years, light and radiant heat are transverse vibrations. Faraday himself did not rest with this theory for electricity alone. The very last time I saw him at work in the Royal Institution was in an underground cellar, which he had chosen for freedom from disturbance; and he was arranging experiments to test the time of propagation of magnetic force from an induction coil through a distance of many yards to a fine steel needle polished to reflect light; but no result came from those experiments. About the same time, or soon after, certainly not long before the end of his working time, he was engaged (I believe at the shot tower near Waterloo Bridge on the Surrey side) in efforts to discover relations between gravity and magnetism, which also led to no result.

Absolutely nothing has hitherto been done for gravity either by experiment or observation towards deciding between Newton and Bernoulli as to the question of its propagation through a medium, and up to the present time we have no light, even so much as to point a way for investigation, in that direction. But for electricity and magnetism, Faraday's anticipations and Clerk-Maxwell's splendidly developed theory have been established on the sure basis of experiment by Hertz's work, of which his own most interesting account is this year presented to the world in the German and English volumes to which I have referred. It is interesting to know, as Hertz explains in his introduction, and it is very important in respect to the experimental demonstration of magnetic waves to which he was led, that he began his electric researches in a problem happily put before him thirteen years ago by Prof. von Helmholtz, of which the object was to find by experiment some relation between electromagnetic forces and dielectric polarisation of insulators, without, in the first place, any idea of discovering a progressive propagation of those forces through space.

It was by sheer perseverance in philosophical experimenting that Hertz was led to discover a finite velocity of propagation of electromagnetic action, and then to pass on to electromagnetic waves in air and their reflection, and to be able to say, as he says in a short reviewing sentence at the end of his eighth paper: "Certainly it is a fascinating idea that the processes in air which we have been investigating, represent to us on a million-fold larger scale the same processes which go on in the neighbourhood of a Fresnel mirror, or between the glass plates used for exhibiting Newton's rings."

Prof. Oliver Lodge has done well in connection with Hertz's work, to call attention[3] to old experiments, and ideas taken from them, by Joseph Henry, which came more nearly to an experimental demonstration of electromagnetic waves than anything that had been done previously. Indeed, Henry, after describing experiments showing powerful enough induction due to a single spark from the prime conductor of an electric machine to magnetise steel needles at a distance of thirty feet in a cellar beneath with two floors and ceilings intervening, says that he is "disposed to adopt the hypothesis of an electrical plenum," and concludes with a short reviewing sentence: "It may be further inferred that the diffusion of motion in this case is almost comparable with that of a spark from a flint and steel in the case of light."

Prof. Oliver Lodge himself did admirable work in his investigations with reference to lightning rods,[4] coming very near to experimental demonstrations of electromagnetic waves; and he drew important lessons regarding "electrical surgings" in an insulated bar of metal "induced by Maxwell's and Heaviside's electromagnetic waves," and many other corresponding phenomena manifested both in ingenious and excellent experiments devised by himself and in natural effects of lightning.

Of electrical surgings or waves in a short insulated wire, and

of interference between ordinary and reflected waves, and positive electricity appearing where negative might have been expected, we hear first, it seems, in Herr von Bezold's "Researches on the Electric Discharge" (1870), which Hertz gives as the third paper of his collection, with interesting and ample recognition of its importance in relation to his own work.

In connection with the practical development of magnetic waves, you will, I am sure, be pleased if I call your attention to two papers by Prof. G. F. Fitzgerald, which I heard myself at the meeting of the British Association at Southport in 1883. One of them is entitled "On a Method of Producing Electromagnetic Disturbances of comparatively Short Wave-lengths." The paper itself is not long, and I shall read it to you in full, from the "Report of the British Association," 1883: "This is by utilising the alternating currents produced when an accumulator is discharged through a small resistance. It is possible to produce waves of as little as two metres wave-length, or even less." This was a brilliant and useful suggestion. Hertz, not knowing of it, used the method; and, making as little as possible of the "accumulator," got waves of as little as 10 cm. wave-length in many of his fundamental experiments. The title alone of Fitzgerald's other paper, "On the Energy Lost by Radiation from Alternating Currents," is in itself a valuable lesson in the electromagnetic theory of light, or the undulatory theory of magnetic disturbance. It is interesting to compare it with the title of Hertz's eleventh paper, "Electric Radiation"; but I cannot refer to this paper without expressing the admiration and delight with which I see the words "rectilinear propagation," "polarisation," "reflection," "refraction," appearing in it as sub-titles.

During the fifty-six years which have passed since Faraday first offended physical mathematicians with his curved lines of force, many workers and many thinkers have helped to build up the nineteenth century school of *plenum*; one ether for light, heat, electricity, magnetism; and the German and English volumes containing Hertz's electrical papers, given to the world in the last decade of the century, will be a permanent monument of the splendid consummation now realised.

But, splendid as this consummation is, we must not fold our hands and think or say there are no more worlds to conquer for electrical science. We do know something now of magnetic waves. We know that they exist in nature, and that they are in perfect accord with Maxwell's beautiful theory. But this theory teaches us nothing of the actual motions of matter constituting a magnetic wave. Some definite motion of matter perpendicular to the lines of alternating magnetic force in the waves and to the direction of propagation of the action through space, there must be; and it seems almost satisfactory as a hypothesis to suppose that it is chiefly a motion of ether with a comparatively small but not inconsiderable loading by fringes of ponderable molecules carried with it. This makes Maxwell's "electric displacement" simply a to-and-fro motion of ether across the line of propagation, that is to say, precisely the vibrations in the undulatory theory of light according to Fresnel. But we have as yet absolutely no guidance towards any understanding or imagining of the relation between this simple and definite alternating motion, or any other motion or displacement of the ether, and the earliest known phenomena of electricity and magnetism—the electrification of matter, and the attractions and repulsions of electrified bodies; the permanent magnetism of lodestone or steel, and the attractions and repulsions due to it; and certainly we are quite as far from the clue to explaining, by ether or otherwise, the enormously greater forces of attraction and repulsion now so well known after the modern discovery of electromagnetism.

Fifty years ago it became strongly impressed on my mind that the difference of quality between vitreous and resinous electricity, conventionally called positive and negative, essentially ignored as it is in the mathematical theories of electricity and magnetism with which I was then much occupied (and in the whole science of magnetic waves as we have it now), must be studied if we are to learn anything of the nature of electricity and its place among the properties of matter. This distinction, essential and fundamental as it is in frictional electricity, electro-chemistry, thermo-electricity, pyro-electricity of crystals, and piezo-electricity of crystals, had been long observed in the old known beautiful appearances of electric glow and brushes and sparks from points and corners on the conductors of ordinary electric machines and in exhaustive receivers of air-pumps with electricity passed through them. It was also known, probably as many as fifty years ago, in the vast difference of behaviour of the positive and negative electrodes of the electric arc lamp. Faraday gave great attention to it [1] in experiments and observations regarding electric sparks, glows, and brushes, and particularly in his "dark discharge" and "dark space" in the neighbourhood of the negative electrode in partial vacuum. In [1523] of his 12th series, he says, "The results connected with the different conditions of positive and negative discharge will have a far greater influence on the philosophy of electrical science than we at present imagine." His "dark discharge" ([1544–1554]) through space around or in front of the negative electrode was a first instalment of modern knowledge in that splendid field of experimental research which, fifteen years later, and up to the present time, has been so fruitfully cultivated by many of the able scientific experimenters of all countries.

The Royal Society's Transactions and Proceedings of the last years contain, in the communications of Gassiot,[2] Andrews and Tait,[3] Cromwell Varley,[4] De La Rue and Müller,[5] Spottiswoode,[6] Moultan,[7] Plücker,[8] Crookes,[9] Grove,[10] Robinson,[11] Schuster,[12] J. J. Thomson,[13] and Fleming,[14] almost a complete history of the new province of electrical science which has grown up largely in virtue of the great modern improvements in practical methods for exhausting air from glass vessels, by which we now have "vacuum tubes" and bulbs containing less than 1/190,000 of the air which would be left in them by all that could be done in the way of exhausting (supposed to be down to 1 mm. of mercury) by the best air-pump of fifty years ago. A large part of the fresh discoveries in this province have been made by the authors of these communications, and their references to the discoveries of other workers very nearly complete the history of all that has been done in the way of investigating the transmission of electricity through highly rarefied air and gases since the time of Faraday.

Varley's short paper of 1871, which, strange to say, has lain almost or quite unperceived in the Proceedings during the twenty-two years since its publication, contains an admirable first instalment of discovery in a new field—the molecular torrent from the "negative pole," the control of its course by a magnet, its pressure against either end of a pivoted vane of mica according as it is directed by a magnet to one end or the other, the shadow produced by its interception by a mica screen. Quite independently of Varley, and not knowing what he had done, Crookes was led to the same primary discovery, not by accident, and not merely by experimental skill and acuteness of observation. He was led to it by carefully designed investigation, starting with an examination of the cause of irregularities which had troubled [15] him in his weighing of thallium; and, going on to trials for improving Cavendish's gravitational measurement, in the course of which he discovered that the seeming attraction by heat is only found in air of greater than 1/1000 [16] of ordinary density; and that there is repulsion increasing to a maximum when the density is decreased from 1/1000 to 36/1,000,000, and thence diminishing towards zero as the rarefaction is farther extended to density 1/20,000,000. From this discovery Crookes came to his radiometer, first without and then with electrification, powerfully aided by Sir George Stokes.[17] As he went on he brought all his work more and more into touch with the kinetic theory of gases; so much so that when he discovered the molecular torrent he

immediately gave it its true explanation—molecules of residual air, or gas, or vapour projected at great velocities[1] by electric repulsion from the negative electrode. This explanation has been repeatedly and strenuously attacked by many other able investigators, but Crookes has defended[2] it, and thoroughly established it by what I believe is irrefragable evidence of experiment. Skilful investigation perseveringly continued brought out more and more of wonderful and valuable results: the non-importance of the position of the positive electrode; the projection of the torrent *perpendicularly* from the surface of the negative electrode; its convergence to a focus and divergence thenceforward when the surface is slightly convex; the slight but perceptible repulsion betweed two parallel torrents due, according to Crookes, to negative electrifications of their constituent molecules; the change of direction of the molecular torrent by a neighbouring magnet; the tremendous heating effect of the torrent from a concave electrode when glass, metal, or any ponderable substance is placed in the focus; the phosphorescence produced on a plate coated with sensitive paint by a molecular torrent skirting along it; the brilliant colours—turquoise-blue, emerald, orange, ruby-red—with which grey colourless objects and clear colourless crystals glow on their struck faces when lying separately or piled up in a heap in the course of a molecular torrent; "electrical evaporation" of negatively electrified liquids and solids;[3] the seemingly red-hot glow, but with no heat conducted inwards from the surface, of cool, solid silver kept negatively electrified in a vacuum of 1/1,000,000 of an atmosphere, and thereby caused to rapidly evaporate. This last-mentioned result is almost more surprising than the phosphorescent glow excited by molecular impacts in bodies not rendered perceptibly phosphorescent by light. Both phenomena will surely be found very telling in respect to the molecular constitution of matter and the origination of thermal radiation, whether visible as light or not. In the whole train of Crookes' investigations on the radiometer, the viscosity of gases at high exhaustions, and the electric phenomena of high vacuums, ether seems to have nothing to do except the humble function of showing to our eyes something of what the atoms and molecules are doing. The same confession of ignorance must be made with reference to the subject dealt with in the important researches of Schuster and J. J. Thomson on the passage of electricity through gases. Even in Thomson's beautiful experiments showing currents produced by circuital electromagnetic induction in complete poleless circuits, the presence of molecules of residual gas or vapour seems to be *the essential*. It seems certainly true that without the molecules there could be no current, and that without the molecules electricity has no meaning. But in obedience to logic I must withdraw one expression I have used. We must not imagine that "presence of molecules is *the* essential." It is certainly *an* essential. Ether also is certainly *an* essential, and certainly has more to do than merely to telegraph to our eyes to tell us of what the molecules and atoms are about. If a first step towards understanding the relations between ether and ponderable matter is to be made, it seems to me that the most hopeful foundation for it is knowledge derived from experiment on electricity in high vacuum; and if, as I believe is true, there is good reason for hoping to see this step made, we owe a debt of gratitude to the able and persevering workers of the last forty years who have given us the knowledge we have: and we may hope for more and more from some of themselves and from others encouraged by the fruitfulness of their labours to persevere in the work.

The President then presented the medals awarded by the Society as follows:—The Copley Medal to Sir George Gabriel Stokes, Bart., F.R.S., for his researches and discoveries in physical science; a Royal Medal to Prof. A. Schuster, F.R.S., for his spectroscopic inquiries, and his researches on disruptive discharge through gases and on terrestrial magnetism; a Royal Medal to Prof. H. Marshall Ward, F.R.S., for his researches into the life-history of fungi and schizomycetes; and the Davy Medal to Prof. J. H. van't Hoff and Dr. J. A. Le Bel, in recognition of their introduction of the theory of asymmetric carbon, and its use in explaining the constitution of optically active carbon compounds.

In the evening the Fellows and their friends dined together at the Whitehall Rooms, Hôtel Métropole.

[1] Probably, I believe, not greater in any case than two or three kilometres per second.

THE TEMPERATURE OF IGNITION OF EXPLOSIVE GASEOUS MIXTURES.

AN important contribution to our knowledge of this subject is communicated to the *Berichte* by Prof. Victor Meyer of Heidelberg, in conjunction with his assistant, Herr A. Münch. The interesting experiments which were carried out some eighteen months ago in the Heidelberg laboratory, concerning the conditions under which the explosion or silent combination of gaseous mixtures occurs, left the question of the precise temperatures of explosive combination undetermined, inasmuch as the necessary high temperatures were attained by the use of boiling salts whose temperatures of ebullition lay a considerable number of degrees apart. The researches have since been continued under conditions in which it has been found possible to determine the actual temperatures with precision. In these experiments any possibility of the occurrence of appreciable amounts of silent combination has been avoided, in order that the determinations of the temperature of explosive combination might be unaffected by errors due to that cause. The conspicuous novelty of the method adopted consists in placing the small bulb containing the mixture to be exploded inside the larger bulb of the air thermometer employed to determine the temperature, thus at once ensuring that the explosion bulb and the thermometer bulb shall be heated to precisely the same temperature. The objection which at first suggests itself, that the heat suddenly developed at the moment of explosion might exert a disturbing influence upon the indications of the air thermometer, was proved by direct and repeated experiment to be without validity, such disturbance being found to be too small to be measured. The bulb in which the explosion is brought about is not closed, for the explosion of such detonating mixtures of gases at rest, that is to say, confined to a closed space, is so violent that if the glass escapes pulverisation it is much distorted, owing to the temperature to which it requires to be heated being about its softening point. The distortion usually takes the form of a shrinking from two opposite points, where the glass is drawn in and distended to such an extent as to produce two internal spheres. Such deformation would of course alter considerably the volume of the air thermometer. This is avoided by attaching a long stem to the bulb, open at the free extremity, and of passing a slow current of the gaseous mixture through the apparatus. The bulb of the thermometer was heated by means of a bath of a fused alloy consisting of equal parts of tin and lead, and it was found immaterial whether the thermometer was directly immersed in the molten metal or protected by means of a closely-fitting refractory metal sheath. The estimation of the temperature was effected by displacing the air of the thermometer, whose volume was known, by means of a current of hydrochloric acid gas, and measuring its volume over distilled water which had recently been freed from air by boiling.

The first series of experiments were made with the detonating electrolytic mixture of hydrogen and oxygen. The gases were freed from ozone by passage through a solution of potassium iodide. They were then washed through water, with which a Woulfe's bottle was almost filled, after which they traversed a tube packed with numerous discs of brass gauze, which were found effectual in preventing the explosion from travelling back to the Woulfe's bottle. The mixed gases were then allowed to enter the explosion bulb by means of a capillary tube passing down the stem to the bottom of the bulb. The rapidity of the gaseous stream was found to exert no influence upon the temperature of explosion, within the limits imposed by the mode of experimenting. The bath was then gradually raised to the neighbourhood of the combining temperature, and the instant the explosion ensued the air contained in the thermometer was displaced by hydrogen chloride, collected over water in the measuring vessel, and its volume ascertained on the attainment of atmospheric temperature and pressure. By displacing the air the instant the detonation was heard, any appreciable augmentation of the temperature during the moment of explosion was prevented.

As the result of several series of experiments carried out with four distinct sets of apparatus, the temperature of explosion of electrolytic hydrogen and oxygen is found to vary from 612° to 686°. It would thus appear, conformable with the supposition of Prof. Van t'Hoff from theoretical considerations, that this mixture is incapable of exhibiting a sharply fixed temperature of explosion. Moreover, it makes no difference whether the mixture is dry or moist; for if dried a small amount of silent

combination invariably renders it again moist before explosion occurs.

It has been currently supposed that the presence of sharp solid fragments, such as those of glass, exerts a lowering effect upon the temperature of explosion of hydrogen and oxygen. This supposition has been practically tested and found wanting in accuracy. Neither glass fragments nor sea-sand were found to reduce the temperature below the limits above stated. A remarkable result, however, was obtained when pieces of platinum foil and wire were introduced into the explosion bulb. It was found impossible in their presence to bring about an explosion, even when the temperature of the bath was raised to 715°. Quiet combination invariably ensued.

The size of the explosion vessel appears to be immaterial, except when reduced to very small dimensions, such as 4·5 mm. diameter, as in the case of the smallest bulb tested, when the range of molecular forces is approached. In six experiments with this small bulb no explosion occurred; in others the explosion did not occur in the vessel, but the quiet combustion there initiated was transmitted along the leading tube, through the tube containing the brass gauze discs, and eventually occasioned an explosion in the wash-bottle, disastrous to the latter.

In the cases of other explosive mixtures the admixture was effected, in the proper proportion, in a three litre flask, from which the gases were driven first through a wash-bottle, and subsequently through a test-tube, arranged likewise as a small safety wash-bottle, to prevent the explosion reaching the larger one.

Carbon monoxide and oxygen, in the proportion to form carbon dioxide, were found to suffer, for the most part, silent combination in the apparatus, and the wide limits of the observed temperatures of explosion, 636° to 814°, in those cases when explosion did ensue, were found to be due to more or less of such silent combination.

Gaseous mixtures of hydrocarbons and oxygen were found, however, with the exception perhaps of marsh gas and oxygen, to exhibit practically no quiet combination; and these mixtures have afforded most trustworthy and constant temperatures of explosion.

Marsh gas was found to explode, as a rule, with oxygen at temperatures varying from 656° to 678°, but occasionally quiet and complete combustion occurred. Other hydrocarbons never failed to yield an explosion.

Ethane detonated with oxygen in three experiments at 622°, 605°, and 622° respectively. A mixture of ethylene and oxygen exploded at 577°, 590°, and 577° in three consecutive experiments. Acetylene prepared by Gattermann's method, which in Prof. Meyer's experience yields it in a purer state than the more recent convenient method discovered by Maquenne, explodes with oxygen with exceptional violence, the wash-bottle being destroyed in every experiment. The temperature of this explosion was very constant, 510°, 515°, and 509° being successively observed. Propane mixed with five times its volume of oxygen likewise exhibits a very constant temperature of ignition, 548°, 545°, and 548° being indicated in three determinations. Propylene exploded with four and a half times its volume of oxygen at 497°, 511°, and 499°. Isobutane mixed with six and a half times its volume of oxygen detonated at 549°, 550°, and 545°; and isobutylene at 546°, 548°, and 537°. Finally, coal gas mixed with thrice its volume of oxygen was found to explode in three experiments at the remarkably constant temperatures of 649°, 647°, and 647°. It was found impossible, however, to induce a mixture of coal gas and air to explode under these experimental conditions.

It will be clearly seen from the above experiments with gaseous mixtures of hydrocarbon and oxygen, that the temperature of explosion falls as the content of carbon increases. Thus the mean temperatures for methane, ethane and propane are 667°, 616°, and 547° respectively. Further, the temperature also falls with the degree of saturation, or in other words, the less saturated the hydrocarbons become the more readily do they ignite in contact with oxygen. Thus ethane, ethylene and acetylene explode with oxygen at 616°, 580° and 511°; propane and propylene at 547° and 504°; and isobutane and isobutylene at 548° and 543°. It will also be observed, however, as would be expected, that these differences due to difference of saturation diminish as the series are ascended.

A. E. TUTTON.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. Austen Leigh, Provost of King's, the Vice-Chancellor, has been appointed a member of the Geographical Committee, in the place of Dr. Ferrers, resigned. The award of the Geographical Studentship of £100 will be made towards the end of the Lent Term.

The first award of the Walsingham Medal, founded by the Lord High Steward for the encouragement of biological research, has been made to Mr. E. W. MacBride, Fellow of St. John's, for his monographs in zoology.

MR. ARTHUR WILLEY, at present giving a course of lectures in Columbia College, New York, has been elected to the vacant Balfour Studentship by the Special Board of Biological and Geological Studies of the University of Cambridge. It is understood that the investigation prescribed for him will be that of the embryology of *Nautilus pompilius*, for which purpose he will proceed to the South Seas.

SCIENTIFIC SERIALS.

The Quarterly Journal of Microscopical Science for September, 1893, contains studies on the comparative anatomy of sponges: V. Observations on the structure and classification of the *Calcarea Heterocœla*, by Dr. Arthur Dendy (plates 10–14). In this paper the author gives a general account of the anatomy, histology, and classification of the *Calcarea Heterocœla*, from the point of view of one who has for a long time past been engaged in an independent study of the group, and he brings together all that is known on the subject. While on the classification of the group he departs somewhat widely from the lines laid down by previous writers, yet the necessity of doing so was forced upon him by a study of nearly fifty Australian species. The author finds neither the canal system nor the skeleton affords a reliable guide for classification, and a compromise is the only satisfactory way out of the difficulty. The families adopted are: (1) Leucasidæ, (2) Sycettidæ, (3) Grantidæ, (4) Heteropidæ, (5) Amphoriscidæ.—On some points in the origin of the reproductive elements in Apus and Branchipus, by J. E. S. Moore (plates 15 and 16). Calls attention to some important details in the spermatogenesis of Branchipus and in the ovigenesis in Apus. In the former, the observations bear out the general law as to the similarity of the male and female cells, their specific peculiarities being physiological in origin, without morphological import. The divisional phenomena of these cells are intimately related to a protoplasmic structure, which might be fitly described as "Schaumplasma," and one of the initial impulses towards metamorphosis is a fusion of some of the intra-nuclear globules; while a considerable portion of the complicated karyokinetic figures, with their centrosomes, pseudosomes, and dictyosomes, appear to be the logical as well as the actual consequence of the continuance of this process. Some time before and always during the course of the chromatic changes bodies answering to the centrosomes in all details except in their numbers, which is much greater, make their appearance; these the author provisionally names "pseudosomes." The term "dictyosomes" is given to bodies which make their appearance connected one to another and to the inner group of chromosomes by fine strands, and which remain uncoloured by reagents, and are more or less related to the cell periphery. (In connection with these, Farmer's notes and figures of like bodies in the Pollen mother-cells is of interest. (See *Ann. of Bot.* September, 1893).—Notes on the Peripatus of Dominica, by E. C. Pollard (plate 17). Miss Pollard's species is apparently very nearly related to *P. edwardsii*, but differs in the number of ambulatory appendages, there being 29 to 34 pairs in *P. edwardsii*, while in *P. dominicæ*, sp. nov., there are from 25 to 30.—Studies on the Protochordata, by Arthur Wiley, B.Sc. (plates 18–20). II. The development of the neuro-hypophysial system in *Ciona intestinalis* and *Clavelina lepadiformis*, with an account of the origin of the sense-organs in *Ascidia mentula*. III. On the position of the mouth in the larvæ of the Ascidians and Amphioxus, and its relations to the Neuroporus.

Symons's Monthly Meteorological Magazine, November. Mr. Symons gives a summary of all the rainfall observations known to have been taken in Persia; the only places at which such appear to have been made are Ooromiah, in the north-

west; Bushire, on the eastern shore of the Persian Gulf, and at Teheran. At Bushire the annual mean for 1878–90 is 12·96 inches. Recent observations at Teheran give a mean of about 10 inches, and the older observations, taken at the Russian Embassy, give a mean of about 11 inches, of which nearly the whole falls in the winter half of the year. To the north of the great mountain range, between Teheran and the Caspian, the fall is nearly four times as great as in Persia. The same number of the magazine contains a summary of the few meteorological papers read at the British Association at Nottingham.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 16.—"Experiments in Heliotropism." By G. J. Romanes, F.R.S.

I cannot find in the literature of heliotropism that any experiments have hitherto been made on the effects of interrupted illumination, when the periods of illumination are rendered as brief as possible—*i.e.*, instantaneous flashes of light. Accordingly I have conducted an extensive research on heliotropism, where the flashes have been caused either by means of electric sparks in a dark room, or by the opening of a photographic shutter placed before the plants in a camera obscura with an arc light or Swan burner, at a distance of several feet on the other side of the shutter. The electric sparks were made either with a Wimshurst machine, induction sparks, or by means of the following contrivance. From the binding screws of the condenser of a large induction coil copper wires were led to a cup of mercury, where, by means of an electro-magnet suitably actuated by clockwork, a current was closed and opened at any desired intervals: each break was therefore accompanied by a brilliant spark. A thick plate of glass was interposed between the seedlings and the electrical apparatus. In all the experiments here described the plants employed were mustard seedlings (*Sinapis nigra*), previously grown in the dark until they had reached a height of between one and two inches. Save when the contrary is stated, in all the experiments comparative estimates were formed by using the same pot of seedlings: during the first half of a comparative experiment half of the seedlings were protected from the light by a cap of cardboard covering half the pot; during the second half of the experiment this cap was removed, and the pot turned round so as to expose the previously protected seedlings to the influence of the light. The principal results thus obtained, and frequently corroborated, were as follows:—

I. Even having regard to the fact that for equal strengths of a stimulus excitable tissues are more responsive in proportion to the suddenness of the stimulus (or in a kind of inverse proportion to the duration of the stimulus), the heliotropic effects of such flashing stimulation as is above described proved to be much greater than might have been antecedently expected. This was shown to be the case whether the effects were estimated by the rapidity with which the seedlings began to bend after the flashing stimulation was begun, or by that with which they continued to bend until attaining a horizontal line of growth, *i.e.* bending to a right angle. Thus, at a temperature of 70° Fahr., and in a moist camera, vigorously growing seedlings begin to bend towards the electric sparks ten minutes after the latter begin to pass, and will bend through 45° in as many minutes; frequently they bend through another 45° in as many minutes more. This is a more rapid rate of bending than can be produced in the same pot of seedlings when the previously protected side is uncovered and exposed for similar durations of time, either to constant sunlight or to constant diffused daylight. This is the case even if the sparks (or flashes) succeed one another at intervals of only two seconds.

II. It would thus appear that the heliotropic influence of electric sparks (or flashes) is greater than can be produced by any other source of illumination. But in order to test this point more conclusively, I tried the experiment of exposing one half-pot of seedlings in one camera to the constant light of a Swan burner, and another half-pot of similar seedlings in another camera, placed at the same distance from the same source of light, but provided with a flash shutter working at the rate of two seconds intervals. The amount of bending in similar times having been noted, the pots were then exchanged and their previously protected halves exposed to the constant and the flashing light respectively. In both cases, the rapidity with which the bending commenced and the extent to which it proceeded in a given time after commencement, were considerably greater in the seedlings exposed to the flashing than to the constant source stimulation. The same is true if, instead of a Swan burner, the source of light is the sun.

III. Many experiments were tried in order to ascertain the smallest number of sparks in a given time which would produce any perceptible bending. Of course the results of such experiments varied to some extent with the condition of the seedlings. But in most cases, with vigorous young mustard seedlings and careful observation, bending could be proved to occur within fifteen to thirty minutes, if bright sparks were supplied at the rate of only one per minute. The most extreme sensitiveness that I have observed in these experiments was that of perceptible bending after half-an-hour's exposure to electrical sparks following one another at the rate of fifty in an hour. This result would appear to indicate that in heliotropism under flashing light there need be no summation or "staircase effect"; but that each flash or spark may produce its own effect independently of its predecessors or successors.

IV. It is noteworthy that, while the heliotropic effects of flashing light are thus so remarkable, they are unattended with the formation of any particle of chlorophyll. In the many hundred pots, and therefore many thousands of plants, which have passed under my observation in this research I have never seen the slightest shade of green tingeing the etiolated seedlings which had bent towards flashing light. On one occasion I kept a stream of 100 sparks per second illuminating some mustard seedlings continuously for forty-eight hours; and although this experiment was made for the express purpose of ascertaining whether any chlorophyll would be formed under the most suitable conditions by means of flashing light, no change of colour in any of the seedlings was produced.

With the exception of those mentioned in the last paragraph, all these results were obtained by using sparks from the coil condenser, as above explained. These sparks were very brilliant, and yielded the maximal results, which alone are here recorded.

"Experiments in Germination." By G. J. Romanes, F.R.S.

The primary object of these experiments was to ascertain whether the power of germination continues in dry seeds after the greatest possible precautions have been taken to prevent any ordinary processes of respiration for practically any length of time.

The method adopted was to seal various kinds of seeds in vacuum tubes of high exhaustion, and after they had been exposed to the vacuum for a period of fifteen months to remove them from the tubes and sow them in flower-pots buried in moist soil. In other cases, after the seeds had been *in vacuo* for a period of three months, they were transferred to sundry other tubes respectively charged with atmospheres of sundry pure gases or vapours (at the pressure of the air at time of sealing); after a further period of twelve months these sundry tubes were broken, and their contents sown as in previous case. In all cases, excepting that of clover, the seeds sown were weighed individually in chemical balances, and seeds of similar weights taken from the same original packets were similarly sown as controls.

The exhaustion of the tubes was kindly undertaken by Mr. Crookes, F.R.S., to whom I must express my best thanks for the assistance he has given. The kinds of seeds used were mustard, red beet, clover, peas, beans, spinach, cress, barley, and radish. In addition to vacuum tubes and control tubes containing air, others were charged with oxygen, hydrogen, nitrogen, carbon monoxide, sulphuretted hydrogen, aqueous vapour, ether, and chloroform.

With the exception of the beans, where only two were sown, ten weighed seeds were sown out of each of the tubes, and also out of each of the control packets which had been kept in ordinary air from the first. These results amply prove that neither a vacuum of one-millionth of an atmosphere, nor the atmospheres of any of the gases and vapours named, exercised much, if any, effect on the germinating power of any of these seeds. I may add that the same remark applies to an atmosphere of carbon dioxide, although in the particular series of experiments quoted this gas was accidentally omitted.

A subsidiary object of these experiments was to ascertain whether any appreciable variations would be caused in plants grown from seeds which, before germination, had been submitted to the conditions above explained. Hundreds of plants

of the kinds named were grown from the seeds in the various tubes. But in no one instance was there the smallest deviation in any respect from the standard type grown from the corresponding control packet.

In the case of the beet-root, a larger number of plants were developed in many of the pots than the ten seeds which had been sown in each. This I found to be due to the fact that beet-root seeds very frequently throw up two seedlings apiece. Not so frequently, but still very often, they yield three, and sometimes even four.

Further experiments are in progress.

"On hepatic glycogenesis," by Dr. Noël Paton, Superintendent, Research Laboratory of the Royal College of Physicians of Edinburgh.

The object of the research is to determine the *mode* of conversion of glycogen to sugar in the liver. Is it due to a zymin, or to the metabolism of the liver protoplasm? A study of the *rate of conversion* of glycogen in the excised liver at the body temperature shows that there is an initial rapid and a subsequent slow stage in the process. The former occurs before visible morphological changes can be detected in the cells; the latter goes on after the cells are disorganised. The former is inhibited by *destroying the cells* (by pounding with sand), and by the presence of one per cent. of *fluoride of sodium;* the latter is not stopped thereby. The *product* of the former is glucose; of the latter, glucose with dextrin and, possibly, maltose. Agents, such as chloroform, ether, and pyrogallic acid, hasten the disintegrative changes in the cells, and accelerate the early rapid stage of conversion, but do not influence the later slower stage. During life the first may produce glycæmia by this action on glycogen conversion. They seem to act by hastening the katabolic changes immediately preceding cellular death. Drugs, such as curare, morphin, and nitrite of amyl, which cause glycæmia, do not do so by increasing the conversion of glycogen; they do not accelerate the morphological changes in the cells. These observations show that the *early rapid changes are due to the metabolism of the protoplasm.* The later slower changes are not due to the *acid* which develops, nor are they, to any marked extent, due to the action of *micro-organism;* they seem to be brought about by a *zymin* developed as a result of the disintegration of the cells.

November 23.—"Magnetic Observations in Senegambia." By T. E. Thorpe, F.R.S., and P. L. Gray.

On the occasion of the recent Eclipse Expedition to Senegambia we took with us a set of magnetic instruments of the Kew pattern, with a view of making observations in a district for which the magnetic elements have not hitherto been determined.

Observations were made at Fundium, Senegal, and at Bathurst, on the River Gambia.

The results are as follows:—

Fundium, Senegal, lat. 14° 7'·4 N., long. 16° 32' W. (approx.).

The observations were made on April 4, 5, and 14, 1893, in the vicinity of the Eclipse Camp and on a partially enclosed piece of ground between the Administrator's house and the River Salûm, about 80 yards from the shore. The temperature during the force observations was about 30° C.

The results are as follows:—

Declination	= 18° 44' W.
Horizontal force	= 0·30409 c.g.s.
Dip	= Needle 1, 29° 9'·1
,, ...	= ,, 2, 29° 8'·2

Bathurst, River Gambia, lat. 13° 28' N., long. 16° 37' W.

The station was on a large piece of open ground and near the centre of McCarthy Square. All the observations taken were made on April 20, 1893.

Declination	= 18° 50' W.
Horizontal force	= 0·30514 c.g.s.
Dip	= Needle 1, 28° 43'·4.
,, ...	= ,, 2, 28° 42'·1.

Physical Society, November 24.—Prof. A. W. Rücker, F.R.S., President, in the chair.—Colonel Maitland, C.B., was elected a member of the Society. Prof. S. P. Thompson then occupied the chair whilst the President read a paper on the magnetic shielding of concentric spherical shells. In this mathematical investigation the author considers cases in which the equipotential surfaces are surfaces of revolution about a line through the centre of the shells, and the permeability (μ) of each shell is constant. Taking the common centre as origin, the potential within any shell is expanded in terms of zonal spherical harmonics, and the ratio of the shielded to the unshielded field determined. The following important result is arrived at, viz. if the permeabilities of the enclosed and external space be the same, then the ratios of the shielded to the unshielded fields are the same *for each harmonic term,* whether the part shielded be external or internal. It is also shown that the shielding effect on external space when a small magnet is placed at the centre of the shell is the same as the shielding effect on the enclosed space when the shells are placed in a uniform magnetic field. The case of a single shell with a small magnet at the centre is next considered where the permeabilities of the internal and external spaces are taken as unity. Here the shielding depends on the ratio of the outer to the inner radius (a_1/a_0). When the thickness of the shell is 1/100 of a_1 the ratio of shielded to unshielded field (Ψ/ψ_0) is 3/13 when $\mu = 500$, and 3/23 when $\mu = 1000$. For $\mu = 1000$, increasing the thickness from a 1/10 to a 1/2 changes the shielding from 1/60 to 1/194, thus showing that after the shell is moderately thick, further increasing the thickness is not very effective. When the small magnet is displaced from the centre of the shell with its axis along a radius, then the shielding effect of the shell is greater on the side towards which the magnet is moved, and less on the opposite side. Thickening a single shell being inefficient, the effect of using two or three shells separated by air-gaps is investigated. Here, as in the case of a single shell, the shielding is improved by adding permeable material either within the inner or without the outer shell. If the inner and outer diameters are given then when the difference in these diameters is small, one continuous shell gives the best result. For a larger difference, two shells separated by an air-gap are much more efficient than a single one, and filling up the air-gap would appreciably diminish the screening effect. When the permeability of the substance is high the best shielding is obtained when the radii of the bounding surfaces of the shells are in geometrical progression. The great value of lamination is shown in the following table, where the volume of the permeable material is expressed in terms of that of the enclosed space, and the shielding in each case being the best.

	Volume of material used.	External field.
Single shell ...	1·0 ...	0·018
Two shells	5·0 ...	0·0006
Three shells ...	4·8 ...	0·00016
Single shell ...	7·0 ...	0·0103

The conditions for the best arrangement in each of the following cases are fully worked out in the paper, viz. Two shells when the largest and smallest radii and the volume of the material used are given; two contiguous shells of different permeablities; and three shells of different permeabilities. The main results of the investigation are that with thin shells lamination is useless, while with thick shells it is essential, if the best effect is desired. Experiments made on actual shells had fully confirmed the theoretical conclusions. Prof. Minchin said the mathematical results were very simply expressed. Although the work was apparently restricted to zonal spherical harmonics, some of the important formulæ apply equally to general spherical harmonics. Referring to the difficulty of shielding by single thick shells, he pointed out that the equation giving the relation between the shielded and unshielded fields with different thicknesses of shell represented a hyperbola with its asymptotes parallel to the axes; hence the shielding tended to a definite limit as the thickness increased indefinitely. Mr. Evershed said he had been engaged for the last two years on the subject of magnetic shielding, with a view to screening measuring instruments from external fields. In such cases it was not possible to use closed shells, and this introduced trouble. The best results he had yet obtained was to reduce the disturbance to about one-fifth. Another difficulty was introduced by the fact of the shields being magnetised by the current passing through the coil, and owing to hysteresis, the permeability was different according as the magnetisation increased or decreased. By using an outer iron shell a great improvement had been effected. To obtain the best results, it was important to have no joints in the shields. A coil frame with two shields of bent iron was exhibited. Mr. J. Swinburne remarked that the subject divided itself into two, shielding of instruments and shielding sources. If a

dynamo itself be shielded, this did not prevent the currents in the leads producing magnetic disturbances. This was very important in ships. By using an alternator with resolving fields all disturbances could be avoided. Dr. C. V. Burton inquired whether by considering the hydrodynamical analogue of a porous material the case of perforated shells could be elucidated? Mr. A. P. Trotter wished to know if the homogeneity of the shield was of much consequence? At Oxford it had been found that a screen of four inches of scrap-iron was better than boiler-plate. Mr. Blakesley asked if the effect of moving a magnet sideways in a sphere had been observed. He thought the mathematics developed in the paper would be useful in working out the magnetic theory of the earth. Prof. S. P. Thompson thought that taking the permeability as constant would not be quite correct, for μ was a function of the magnetisation. Hence in the cases considered the outer shell would be the more permeable. In his reply, the President said scrap-iron in contact was not like clear space, for there were comparatively free paths for the induction at the points of contact. As regards the shielding of the dynamo at Greenwich, Mr. Christie had written to say that the credit was due to the makers of the machine and shields, Messrs. Johnson and Phillips.—Prof. G. M. Minchin read a paper on the action of electromagnetic radiation on films containing metallic powders. After noticing the resemblance of the phenomena exhibited by tubes containing metallic filings shown by Mr. Croft, on October 27, to those of photoelectric impulsion cells, he repeated some of the experiments with filings, and found the same effects when the filings were of ordinary fineness. He also noticed that the experiments did not succeed either when the filings were coarse or very fine. Coarse ones always conducted, whilst very fine filings or powders acting as insulators, except when strongly compressed. To establish a closer connection with the impulsion cells he tried films of gelatine and collodion containing metallic powders. Directions for preparing the films are given in the paper. On inserting such a film in circuit with a battery, key, and galvanometer, it acts as an insulator. To render a small portion conducting, the electrodes on the surface of the film are brought very close together, and one of the wires touched with an electrified body (an electric gas-lighter was often used). This caused a current to pass. The electrodes may then be separated a little further, and the process repeated until any desired portion is rendered conducting. The peculiarity of such a film is that if the circuit be broken at the film, the film becomes an insulator; whereas breaking the circuit at any other point leaves the film conducting. The action of the sparks or charges on the conductivity of the films is attributed to the influence of electric surgings in the wires by the electric discharges. The President read a written communication from Prof. O. J. Lodge, in which the writer suggested that the phenomena of the films, and also of Lord Rayleigh's water-jet experiment (in which water-drops are caused to coalesce by the presence of an electrified body), were due to the range of molecular attraction being increased by electric polarisation. Mr. Blakesley said he had tried Mr. Croft's experiments, and found that conductivity could be established in a tube of filings whilst the circuit was unclosed. Breaking the circuit of a transformer or electromagnet would produce conductivity; hence he concluded that electric surgings were not essential. Another curious experiment was to put the discharging knobs of an electric machine on a photographic plate at a distance of a few inches. On turning the machine a small spark travels slowly along the plate from the negative to the positive knob. On reversing the polarity of the machine the spark travels back along the same path, but if the polarity remains unchanged a second spark usually travels along a different path. Prof. C. V. Boys asked Prof. Minchin whether the films themselves, or the contacts between the electrode and film is made conducting by the sparks? Prof. S. P. Thompson wished to know if ordinary photographic dry-plates would serve the purpose? Mr. Evershed inquired whether the metal used as electrode made any difference? Prof. Minchin, in his reply, maintained that the phenomena were due to electric impulses. He had not tried photographic plates, and had always used platinum for his electrodes.

Chemical Society, November 16.—Dr. Armstrong, President, in the chair.—A letter has been addressed to Prof. Mendeléef, congratulating the Russian Chemical Society on the celebration of its twenty-fifth anniversary. The following papers were read:—The normal butylic, heptylic, and octylic ethereal salts of active glyceric acid, by P. Frankland and J. MacGregor. The authors have determined the rotatory powers of the homologous series of ethereal salts of active glyceric acid up to octylic glycerate; the molecular rotations of the normal and secondary butylic salts are greater than those of any others of the series. This kind of result has been predicted by Guye.—The ethereal salts of diacetylglyceric acid in relation to the connection between optical activity and chemical constitution, by P. Frankland and J. MacGregor. The authors have prepared the methylic, ethylic, propylic, isopropylic, and isobutylic salts of active diacetylglyceric acid. In the case of the first two of these salts, two of the atomic groups attached to the assymetric carbon atom are of equal mass; according to Guye's theory, these should be almost, or quite, optically inactive. This, the authors find, is not the case. and they therefore again urge that the qualitative nature of the groups attached to the assymetric carbon atom must be considered, as well as their masses.—The oxidation of paratoluidine, by A. G. Green. The red base obtained by Barsilowsky by oxidising paratoluidine with ferrocyanide is a diparatolylimide of the constitution

$$\mathrm{MeC}\left\langle\begin{matrix}\mathrm{C:(NC_7H_7)\cdot CH}\\ \mathrm{CH\cdot C:(NC_7H_7)}\end{matrix}\right\rangle\mathrm{CNH_2}$$

On reduction it yields a stable leuco-base.—The action of benzoic chloride on urine in presence of alkali. Formation of benzoic derivatives of urochrome, by J. L. W. Thudichum. By the action of benzoic chloride on alkaline urine, a mixture of benzoic derivatives of urochrome is deposited.—The combination of hydrocarbons with picric acid and other nitro compounds, by W. A. Tilden and M. O. Forster. Picric acid combines with terpene, giving a compound which forms a peculiar potassium salt, yields picramide and borneol when treated with alcoholic ammonia, and gives borneol when treated with aqueous alkalis.—The formation of pyrrol derivatives from aconitic acid, by S. Ruhemann and F. E. Allhusen.—The conversion of α hydrindonoxime into hydrocarbostyril, by F. S. Kipping. α-hydrindonoxime yields hydrocarbostyril when treated with phosphorus pentachloride.—The constitution of lapachol and its derivatives. II. The azines of the lapachol group, by S. C. Hooker. The author describes methyllapazine, methyllapeurhodone, methylhydroxylapeurhodone, and several of their halogen derivatives.

Geological Society, November 22.—W. H. Hudleston, F.R.S., President, in the chair.—The following communications were read:—The basic eruptive rocks of Gran, by Prof. W. C. Brögger. In previous communications the author has maintained that the different masses of eruptive rock which occur within the sunken tract of country lying between Lake Mjösen and the Langesundsfjord are genetically connected, and have succeeded each other in regular order. The oldest rocks are the most basic, the youngest (except the unimportant dykes of diabase) are the most acid, and between the two extremes he has found a continuous series. He is now preparing a detailed monograph on this series of eruptive rocks, and in the present communication he gave an account of the results of his work on the oldest members. Several bosses of basic plutonic rock, now forming a series of dome-shaped hills, lie along a north-and-south fissure line. The most northerly is that of Brandberget in the parish of Gran, about 50 or 60 kilometres north-north-west of Christiania, and the most southerly occurs at Dignaes on Lake Tyrifjord, about 35 kilometres west-north-west of the same town. The prevailing rock in these bosses is a medium or coarse-grained olivine-gabbro-diabase; but pyroxenites, hornblendites, camptonites, labrador-porphyrites, and augite-diorites also occur. Analyses of the typical rocks from three localities on the north and south line were given, and the conclusion was reached that the average basicity of the rocks forming different bosses decreases from north to south. The contact-metamorphism was referred to; and the presence of hypersthene in the altered *Ogygia*-shales, coupled with its absence from the same shales where they have been affected by quartz-syenite, led the author to the conclusion that the chemical nature of the intrusive rock does, in certain cases, produce an influence on the character of the metamorphism. Innumerable dykes and sheets of camptonite and bostonite are associated with the above-mentioned plutonic bosses. These are regarded by the author as having been produced by differentiation from a magma having the composition of the average olivine-gabbro-diabase. Analyses were given, and it was proved that a mixture of nine parts of the average camptonite and two of the average bostonite would produce a magma

having the composition of the average olivine-gabbro-diabase. The petrographical variations, such as the occurrence of pyroxyenites and augite-diorites, in the plutonic masses themselves are described, and attributed to differentiation under physical conditions unlike those which gave rise to the camptonites and bostonites. In discussing the general laws of differentiation the author pointed out that it must have taken place before crystallisation to any extent had occurred, because there is a marked difference in mineralogical composition between the rocks occurring as bosses and those occurring as dykes; and, further, that it is dependent on the laws which determine the sequence of crystal-building, in so far as the compounds which, on given conditions, would first crystallise are those which have diffused to the cooling margin, and so produced a contact-stratum, of peculiar chemical composition, before any crystallisation had taken place. A discussion followed, in which the President, Prof. Judd, General McMahon, Prof. J. F. Blake, and Mr. W. W. Watts took part.—On the sequence of perlitic and spherulitic structures (a rejoinder to criticism), by Mr. Frank Rutley. This paper related to the order in which the perlitic and spherulitic structures have been developed in a felsitic lava of Ordovician age from Long Sleddale, Westmoreland. The author having described this rock in a paper published in the Quarterly Journal of the Society in 1884, and the accuracy of the views then expressed having been questioned, endeavoured to confirm his original statements, adducing in support fresh observations made upon this and other rocks of a similar kind. Mr. Marr and Dr. J. W. Gregory spoke on the subject of the paper, and the author briefly replied.—Enclosures of quartz in lava of Stromboli, &c., and the changes in composition produced by them, by Prof. H. J. Johnston-Lavis. The author described the existence of enclosures of quartz in a lava-stream at the Punta Petrazza on the east side of Stromboli, and also in the rock of the neck of Strombolicchio. He described the effects of the rocks upon the enclosures, concluding that the quartz has undergone fluxion but not fusion, and has supplied silica to the containing lavas, thus causing an increase in the amount of pyroxene and a diminution in the amount of magnetite in the portions of those lavas that surround the inclusions and raising the percentage of silica. He suggested that such a process at greater depths and higher temperature may, under certain conditions, convert a basic rock into a more acid one, so that possibly the andesite of Strombolicchio may have been of basaltic character at an earlier period of its progress towards the surface. He offered the suggestion that other rocks or minerals once associated with the quartz have been assimilated by the magma. The President and Prof. Judd made a few remarks upon the paper.

Cambridge.

Philosophical Society, October 30.—Prof. Hughes, President, in the chair.—The following officers were elected for the ensuing session:—President, Prof. Hughes; Vice-Presidents, Prof. Cayley, Prof. Darwin, Dr. A. Hill; Treasurer, Mr. Glazebrook; Secretaries, Mr. Larmor, Mr. Newall, Mr. Bateson; New Members of Council, Prof. Sir G. G. Stokes, Dr. Lea, Mr. Shipley, Mr. Seward.—The President (Prof. Hughes) read a paper on the geological evidence for the recurrence of ice ages. Prof. Hughes pointed out that the advocates of the astronomical explanation of glacial ages have urged that there has been a recurrence at regularly varied intervals of combinations, the result of which must have been circumpolar vicissitudes of climate; and, seeing that the secular recurrence of these conditions formed a necessary part of their theory, they gladly welcomed any confirmation of it, such as was offered by those geologists who saw in the character of the stones in certain conglomerates traces of ice-action in several successive geological periods. The value of this evidence he now criticised. He laid before the Society examples of the striated boulders and rock floors supposed to present glaciated surfaces, and with a view to the elimination of sources of error in the identification of the work of ice he exhibited a large series of specimens illustrating the various ways in which results were produced sometimes exactly the same as, and often closely resembling, the forms, markings, and other characters relied upon as proofs of ice action. By reference to these he showed that the facetted stones from which the extension of the glacial conditions over parts of Southern Germany was inferred, found their exact counterparts among those trimmed by blown sand into roof-like forms and ridges, and had no parallel among undoubtedly glacially-dressed stones. The scratched stones in the base of the New Red, or so-called Permian of England (with the exception of one single specimen, which he said must have got into the collection in Jermyn Street by mistake), he compared with those produced by earth movements, in which the included pebbles of the conglomerate were protruded through the softer matrix and scored and indented by harder fragments held in the mass. The supposed glaciation of the boulders in the basement beds of the carboniferous he explained in the same way, producing examples in which the matrix and included fragments were scored alike by movements along small fault faces. He exhibited a portion of the solid silurian floor on which these conglomerates rested, which was striated in a manner that might be easily mistaken for glacial action; but he explained that he had taken this from a thrust plane, and he pointed out the difference in the mineral condition of the surface between these slickensided surfaces and those produced by glacial action. He excluded from the present discussion cases in which ice agency was inferred only from the size and shape of the stones or their isolation in finest material. He admitted the probability of evidence of ice action being found along known axes of recurrent upheaval, such as those in the most ancient rocks along the Scandinavian range, or in the more recent deposits along the Alpine chain, or further south in the carboniferous boulder beds of India, Africa, and Australia; but he pointed out that these last, at any rate, could lend no support to the astronomer's contention, seeing that they surrounded a basin whose centre was in equatorial, not in circumpolar regions. He was willing to admit that in the astronomical combinations we might find a *vera causa* of vicissitudes of climate, but he urged that all the evidence from direct observation went to show that extreme glaciation does and did always bear a direct relation to earth movements.

Academy of Sciences, November 27.—M. de Lacaze-Duthiers in the chair.—On the registration of the variable elements of the sun, by M. H. Deslandres.—On equations and implicit functions, by M. Pellet.—On surfaces admitting of gauche cubics for asymptotic lines, by M. Blutel.—On ripples (*clapotis*), by M. E. Guyou. Equations are obtained in which elliptic functions are substituted for the circular functions employed by Boussinesq. According to these equations, each molecule oscillates along a straight line of fixed direction which itself oscillates vertically, and the resultant motion takes place along a parabola whose axis is vertical. For the surface molecules, the first movement is that of the projection upon the minor axis of an ellipse of a point describing the contour of the curve with a constant linear velocity. On examining the photographic tracing obtained by M. Marey it is found that the motion of the surface molecules takes place along a very flat closed curve. This divergence from the theory is easily explained by the oscillations of the cylinder producing in the experimental basin a vertical displacement of the layers which are theoretically at rest. The superposition of this motion upon that indicated by the theory has the effect of separating in a vertical sense the trajectories corresponding to the two inverse phases of an oscillation.—Mutual action of bodies vibrating in fluid media, by MM. Berson and Juppont. Two vertical discs were placed in air with their axes coincident. The one was made of steel, 0·033 cm. thick and 12 cm. in diameter, and was kept vibrating by two small electromagnets, excited by currents of intensities, varying according to the amplitudes required. The other was of mica, 0·012 cm. thick and 6 cm. in diameter, fixed normally to the bent end of a light bar of aluminium, which, supported by a long silver wire, formed the movable part of a torsion balance. The movement of this disc is due to the surrounding air, thus being analogous to electrostatic induction. The experiments were made inside a cage draped with soft and loose cloth, to prevent resonance. The torsion was measured with a Vernier micrometer to $\frac{1}{10}$ degree. The attractions exhibited between the two discs when vibrating ranged from half a dyne to about 600 dynes. At a distance of 1 mm. it was 602·3 dynes; at 2 mm., 98·0; at 4 mm., 14·5, and at 10 mm., 2·55. To produce the same forces electrostatically, a difference of potential of 600 volts would be required. The authors intend to study the effect of distance and of the medium in the case of pulsating spheres.—Calculation of the forces to which bodies placed in an electromagnetic field are subjected, by M. AMSTERDAM.

Royal Academy of Sciences, October 28.—Prof. van de Sande Bakhuysen in the chair.—Prof. Behrens treated (1) on the structure of native gold. Several samples of auriferous quartz were examined under the microscope, on the supposition that they would be found to contain agglomerated granules of metal. The gold was found to be crystallised in cubes, and in combinations of the cube with the octahedron, so perfectly as even to present good cleavage planes. It would appear, therefore, that such gold must have been precipitated and crystallised at the same time and under the same conditions as the surrounding quartz. Further evidence for this conclusion was afforded by the presence of microscopical cavities in small nuggets. Like the cavities in quartz, they occur in streaks and small heaps, being partly spherical or oval, and partly of a subangular shape. By the distribution of the alloyed silver in concentric layers of rich and poor alloy, the supposition of a molten state is excluded. All these peculiarities were also found in grains of gold washed from an auriferous ochre, enclosed by auriferous quartzite. (2) On the chemical constitution of alloys. (i.) Lead was found to be a good solvent for crystallising copper and its alloys, a small quantity of lead only being taken up by the latter. If a piece of copper is put into red-hot lead containing a little tin, the surface of the copper is changed to bronze, which does not melt, but will partly dissolve in the lead, and on cooling separate out in crystals. Bronze and common brass will not split up into definite alloys under this treatment. The alloy of copper with 10 per cent. aluminium, which is said to be homogeneous, behaves differently. It will yield red crystals in the upper part of the button, yellow ones in the middle, and white ones near the bottom of the crucible. (ii.) Is copper in bronze univalent or bivalent? With a view to solving this question, a series of silver-tin alloys was compared with corresponding bronzes. The following results were obtained: Regular crystals, Cu_6Sn and Ag_6Sn, Cu_3Sn and Ag_3Sn, CuSn and AgSn, $CuSn_2$ and $AgSn_2$; other systems (rhombohedric?) Cu_4Sn and Ag_4Sn (maximum of hardness), Cu_2Sn and Ag_2Sn (second maximum), Cu_2Sn_3 and Ag_2Sn_3. Now, for Ag_4Sn, no other structural formula can be admitted than $Ag_2 = Sn = Ag$, hence there is a great probability for the univalent character of copper in its alloys with tin. Several of the other formulæ will probably have to be doubled. The formula Ag_6Sn cannot be construed here, and the reasoning leads to the supposition that also in bronzes rich in copper the surplus of the predominant metal is simply dissolved in an isomorphous combination.—Prof. Schoute treated on regular sections and projections of the ikosatetrahedron. The author studied the central sections perpendicular to, and the orthogonal projections in, the direction of four lines that join the centrum to a vertex, or to the centre of an edge, of a triangular face, or of a bounding octahedral three-flat. As to the vertices, the four dimensional being L_a^{24} (24 = number of bounding three-flats, a = length of edge), proves to be the combination of a L_a^8 (tessaract) and a $L_{a\sqrt{2}}^{16}$ or of three L_a^8's; as to the bounding three-flats it may be considered as the combination of a L_{2a}^{16} and a $L_{a\sqrt{2}}^8$ or of three L_{2a}^{16}'s.—Prof. Kamerlingh Onnes gave a comparison made by Dr. Zeeman of his measures of polar reflection of light on magnets with the theories of Goldhammer and Drude. His experiments decide in favour of the first theory. Prof. Onnes communicated also an explanation by Dr. Kuenen of the abnormal phenomena observed in the neighbourhood of the critical temperature by the theory of mixtures. The experiments of Dr. Kuenen agree with the results of Gouy.

CONTENTS.

THURSDAY, DECEMBER 14, 1893.

A BOOK OF PRACTICAL EXAMPLES IN ELECTRICITY.

Problèmes et Calculs Pratiques d'Électricité. Par M. Aimé Witz. (Paris: Gauthier-Villars et Fils, 1893.)

THIS is, in the main, a book of fully worked-out exercises in electricity and magnetism, designed for the help of practical students. Its idea and arrangement are good, and the examples seem to have been chosen with much care, and, as far as possible, from actual cases which have occurred in laboratory and practical work. The aim of the author has not been to furnish a set of examples, like the collection of Walton, in theoretical mechanics, or that of Hall Turner, in heat and electricity. These works illustrate general mathematical theories by examples, the solutions of which are in many cases important or interesting particular theorems; but their interest is, to a great extent, mathematical. M. Witz has had in view the wants of students endeavouring to obtain a sound elementary knowledge of electricity, who are not afraid of a piece of calculation involving, when necessary, a little differentiation or integration, when it comes in its proper place as the simplest and most direct means of attaining the required result.

The work is divided into three parts: (1) containing definitions and formulas, (2) numerical constants, and (3) the greater portion of the book—a collection of illustrative examples. Part 1 deals first with magnetism, and gives the ordinary relation between magnetic intensity and magnetic induction, introduces the notions of magneto-motive force and magnetic resistance, and shortly states the main facts of lamellar and solenoidal magnetisation. In like manner the next chapter *states*, merely, some of the principal theorems of electrostatics; the third deals with phenomena of steady currents; and the last two with electro-magnetism and induction of currents.

In connection with electro-magnetism a paragraph is devoted to the researches of Ewing and "M. Hopkins" on the magnetization of iron. All the latter experimenter (the distinguished inventor of characteristic curves of dynamos appears to be meant!) is credited with is a demonstration that the "travail" (consumed in putting a sample of iron through a magnetic cycle) "exprimé en ergs et rapporté à l'unité de volume, est égal au produit de la force coercitive de l'échantillon par l'induction maximum, divisé par π." The measure of coercive force assigned by Hopkinson does not seem to be explained in the book, and so a really important idea, rendering definite what was before a perfectly vague expression, is passed over. As to the demonstration referred to, we must confess to never having heard of it. Dr. Hopkinson, we had supposed, simply used the rule stated in the quotation as a rough and ready method of rapidly finding the approximate dissipation of energy in a closed magnetic cycle.

Ampère's law ("formule classique, connue de tous nos lecteurs") of the action between two current elements is explained, but no hint is given that any number of other laws can be obtained which give for the only cases with which we can without ambiguity deal, those of closed circuits, precisely the same result as is given by Ampère's formula, although the latter may have certain advantages in point of simplicity.

The word "law" is a good deal misused in electrical science; we have Kirchhoff's laws, Ohm's law, Joule's law, Lenz's law, and many others; but we have here a law that we do not remember to have come across before, namely "Pouillet's law," which asserts that the quantity of electricity conveyed by a current I in time t is It! No doubt if the electro-magnetic definition and measure of a current are adopted, it is a proper subject of investigation to settle whether it is simply proportional to the current defined electrostatically as the time rate of flow of electricity; but the real proof that this is the case, is the consistency with the results of experiment of the great mass of results deduced from this proportionality.

The chapter on induction is brief, but contains a great deal of information very accurately expressed. The function of the current which multiplied into the speed gives the electromotive force of a dynamo, is referred to as the "fonction caracteristique" of M. Marcel Depres; but Hopkinson's extremely important dynamo characteristic curves are merely referred to, without any mention of their author.

The so-called law of Jacobi, namely, that "Le travail utile d'un moteur est maximum lorsque sa force contre-électromotrice est égale à la moitié de la force électromotrice de la generatrice," is no doubt correctly stated, since by "le travail utile" is meant the electrical work done on the motor in a given time, otherwise than in heating its conductors. But it would be better to say that the electrical activity as specified in the motor is a maximum when the condition stated is fulfilled. The phrase "useful work," here used, has caused this result, simple as it is, to be completely misunderstood by many practical electricians of high standing. In the present case the tendency to error is obviated by the statement immediately following, that "Le rendement electrique d'une transformation d'energie, est égal au rapport de la force contre-électromotrice e de la réceptrice à la force électromotrice E de la géneratrice. Ce rendement peut devenir egal à l'unité lorsque e devient egal à E; mais alors le travail produit tombe à zéro. C'est la *loi de Siemens*."

The late Sir William Siemens objected in 1883 to the erroneous interpretation put upon Jacobi's result by Verdet and others, and likewise stated the true principle of efficiency; but the law of maximum efficiency of a circuit containing a motor was given in Lord Kelvin's very important paper on the "Mechanical Theory of Electrolysis," published in 1851 in the *Philosophical Magazine*. As not only this result, but others, forming practically the whole of the simple but immensely important elementary theory of the electrical efficiency of a generator and motor, are there incidentally given by Lord Kelvin, and are usually stated in practical treatises and lectures as theorems of much later date, we may be allowed to give here a short abridgement of the passage.

Denoting by ω the angular velocity with which a Faraday disk magneto-electric machine is driven, by Ω the velocity with which the machine would have to be driven to give a back electromotive force equal to that of the generator (a battery in this case), Lord Kelvin

points out that if ω is less than Ω, the current is opposed to the electromotive force of the disk, and that therefore in this case "the chemical action is the source of the current instead of being an effect of it; and the disk by its rotation produces mechanical effect as an electromagnetic engine" (or, as we now call it, a motor) "instead of requiring work to be spent upon it to keep it moving as a magneto-electric machine." If γ' be the current flowing, F the intensity of the field in which the disk revolves, r the radius of the disk, R the resistance of the circuit, W′ the rate at which work is done by the current on the engine, M′ the rate at which energy is spent by the battery, then the results—

$$\gamma' = \frac{r^2 F}{2R}(\Omega - \omega),$$

$$W' = \tfrac{1}{2} r^2 F \omega \gamma',$$

or

$$W' = \frac{\omega}{\Omega} M'$$

are given, and it is pointed out that the fraction of the "entire duty of the consumption which is actually performed by the engine is equal to ω/Ω." The ratio ω/Ω is the ratio of the back electromotive force of the motor to the total electromotive force of the generator, and is therefore the law of efficiency stated above in the words of M. Witz.

The examples worked out in the book are many of them highly instructive, and, so far as we can judge from the examination of a selected few, seem clearly and correctly dealt with. They are not merely numerical, but include in most cases the deduction from general theorems of formulas for particular cases, which are then illustrated by numerical problems in which results are expressed in C.G.S. units. The value of these problems is enhanced by the fact that they are, as we have said, for the most part actual problems which have turned up in experimental or practical work. The subjects thus elucidated include magnetism, electrostatics, steady flow of electricity, electro-magnetism, dynamos, motors, and the distribution and transmission of electric energy. There can be no doubt that the book will prove very useful to teachers and students. Its only fault is that it leaves nothing for the student himself to do. A moderate number of unworked examples, on which he might test his grip of the subject, and power of applying principles, would have been very valuable. It is undesirable to spend very much time in solving mere arithmetical or algebraic conundrums, but enough must be done to acquire a fair amount of readiness and expertness of calculation; and of the great benefit derived from working out numerical examples of physical principles, there can be no doubt. We think, therefore, the author would do well to supply material for this in a future edition.

A. Gray.

BESANT'S DYNAMICS.

A Treatise on Dynamics. By W. H. Besant. (Cambridge: Deighton, Bell, and Co., 1893.)

THIS popular text-book has now reached a second edition, and contains several additions which have increased its size from 334 to 448 pages. A new chapter has been added on disturbed elliptic motion, which shows how the elements of an elliptic orbit are affected by small disturbances in the same plane. This chapter will serve as a useful introduction to the planetary theory, since the limitation of the problem to two-dimensional motion enables various difficulties, which arise from taking into account the longitude of the node and the inclination of the orbit, to be got rid of. The principle, upon which the method of the variation of the elements is based, is one to which students should be introduced at an early stage; but unless some simplification is made, the analysis becomes rather complicated. We are inclined to suggest that this chapter might be extended in a future edition.

The last chapter of the first edition has been amplified into two, the first of which deals with motion in three dimensions, whilst the second discusses several important problems relating to the motion of tops, discs, gyroscopes, &c.; and the book concludes with a new chapter on Lagrange's equations, together with several applications illustrating their use. To discuss any of the higher developments of this branch of the subject, including the Hamiltonian transformation, and the mixed transformation which in 1887 was for the first time given in a *complete* form by the author of this review, would probably be thought beyond the scope of an elementary work; but it would be well to bring out more pointedly the fact that the kinetic energy of a dynamical system can be expressed in several different forms, and that when employing Lagrange's equations there is only one form which it is permissible to use, viz. the Lagrangian form, in which the kinetic energy is expressed as a homogeneous quadratic function of velocities which are the time-variations of coordinates. Mistakes are frequently made upon this point; and it is most necessary to impress upon the minds of students that Lagrange's equations are double-edged tools, which are apt to cut the fingers of those who unskilfully handle them.

Dr. Besant has used the word *phoronomy* in the place of *kinematics*, and he has stated his reasons for so doing in a letter published in NATURE, March 17, 1892. The word appears to be a good one, and has the merit of being classical, and not Teutonic; but notwithstanding occasional flights into the regions of radicalism, the ingrained conservatism of the English mind is so strong that it is by no means certain whether phoronomy will supplant a word which has long held the field.

One of the most satisfactory features of the work is that Dr. Besant has drawn marked attention to the principle of momentum. This principle is in some respects a more fundamental one than the principle of the conservation of mechanical energy; for the former principle is true in the case of viscous systems in which there is a conversion of mechanical energy into heat, whilst the latter does not hold good when internal friction or viscosity exists. The principle of linear momentum can be shown to be a direct consequence of Newton's second and third Laws of Motion; but doubts have been entertained whether the principle of angular momentum can be deduced from Newton's Laws without the aid of an additional hypothesis. The question, however, is far too recondite a one to be discussed in a review.

It is possible that some of those whom a recent correspondent in NATURE has described as "the slug and the bug school" may object to the large amount of problems

and examples which are contained in the text and at the end of the chapters. Persons whose curiosity is limited to finding out *what electricity does*, and adopt the unscientific attitude of considering it waste of time to try and ascertain *what electricity is*, and *why* it is capable of performing so many wondrous feats, may perhaps rebel against a system, one of whose objects is to train the mind to inquire into the *causes* of natural phenomena. It must be recollected that young men, who are just emerging from the schoolboy stage of existence, invariably find that Rigid Dynamics is a very difficult subject to master, and that a thorough knowledge of the principles of the subject, combined with analytical skill in applying them to natural phenomena, can only be acquired by working out a large number of problems and examples. It is also an excellent plan for students to work out the same problem (for example, the motion of a top) by various methods, and to study the different results obtained by each; for they will thereby not only obtain analytical skill, but will learn that their symbols, instead of representing mere mathematical quantities, are the embodiment of important scientific facts.

A. B. BASSET.

INSECT PESTS.

Our Household Insects: an Account of the Insect Pests found in Dwelling-houses. By Edward A. Butler, B.A., B.Sc.Lond., author of "Pond Life," "Silkworms," &c. (London and New York: Longmans, Green and Co., 1893.)

MR. E. A. BUTLER has done useful service to the cause of popular entomology by reprinting the present series of his contributions to *Knowledge* in book form. Not very many species are discussed, but these seem to comprise most of the principal insect pests belonging to the various orders of insects which infest our houses, and attack ourselves or our property.

As insects (exclusive of insect-parasites) attack all kinds of dead or decaying animal and vegetable matters, and play the part of general scavengers, nothing is exempt from their ravages. Books are particularly subject to their attacks; and many of their enemies are noticed by Mr. Butler. We remember once being much amused by an account of a book-worm, which was ridiculed by a writer in a bibliographical magazine, as being evolved from the describer's own consciousness, but which was really fairly recognisable as applicable to *Lepisma saccharina*, the common silver-fish. But the critic regarded the book-worm as necessarily a small grub or beetle (we forget which), and displayed his own ignorance of entomology accordingly. Prof. Westwood once named a minute beetle, which had done much mischief to the cover of a book, *Hypothenemus eruditus*; and specimens of books damaged by insects may be seen in one of the cases in the public insect-room at the Natural History Museum, South Kensington. We believe that Mr. Zaehnsdorf, the well-known book-binder, has also formed a collection of the book-pests which he has met with in the exercise of his vocation. We may add that the Arabs sometimes write the name Kabikaj, said to be that of a genius who presides over insects, on their manuscripts, in order to protect them from the ravages of his subjects.

There is no doubt that insects of various kinds get mixed with human food from time to time; but we imagine that the passage which Mr. Butler quotes from Curtis's "Farm Insects," relating to maggots in cocoa-beans, is somewhat out of place at the end of a chapter on beetles, for we have good reason to believe that the insect to which Curtis alluded was not a beetle, but a moth of the genus *Ephestia*.

The seven plates of magnified insects and their structure, and the numerous woodcuts, add much to the usefulness of the book. Clear definitions, and accurate demonstrations, are extremely useful in entomology, not merely to beginners, but even to more advanced students, who often find much difficulty in obtaining the necessary explanations of the characters and terminology, when they take up the study of a group of insects with which they were not previously familiar.

The insects which Mr. Butler discusses may be divided into three classes: those which really cause serious destruction to property, as the clothes-moths and various kinds of small beetles; those which are rather troublesome and annoying than destructive, such as the flies and wasps; and those which attack man himself. Among the latter are the lice, which the increase of cleanliness has fortunately rendered rather unfamiliar objects to the better classes in recent times. Yet they are highly interesting creatures, from many points of view, and several entomologists have not scrupled to make a special study of them; among others, Denny, who wrote an elaborate monograph on the British species, illustrated with twenty-six coloured plates; and the old Dutch naturalist, Van Leeuwenhoek, who actually reared a brood in a stocking on his own leg! We think the figure of the proboscis of a louse, which Mr. Butler copies from the Danish entomologist Schiödte, on p. 332, will be new to most of his readers. But there is a curious omission of a necessary explanation in Mr. Butler's observations, in the following passage:—

"Man is not exceptional among mammals in harbouring these vermin; he is but in the same category with the rest, for it seems to be the rule, from elephant to mouse, largest to least, that some member of this group of parasites should be attached to each species; and even aquatic animals, such as the seal and walrus, do not evade their attacks."

Surely Mr. Butler, to avoid being misunderstood, should here have stated that the presence of a true louse on seals is quite an exception as regards marine animals, and that the so-called "whale-louse," and similar parasites, are not true lice, or even insects at all, but parasitic crustacea.

Our author mentions the fact of colonies of fleas having sometimes been found on sandy sea-shores, and wonders what they can find to eat there. But although certain species of fleas are attached to different species of animals, they are perhaps not so particular about their food as is generally supposed. In all warm countries it is very common to find colonies of fleas camping-out in the open; and the late Mr. F. Smith once recorded an instance of a suburban garden, in which a particular bed was swarming with dog-fleas; no particular dog being mentioned as the probable origin of the invasion. In the Western States of America, the "wild fleas," as the late

Frank Buckland would have said, actually feed on the larvæ of a white butterfly which abounds in the pine-forests.

Some curious stories are related by Mr. Butler respecting Longicorn beetles, and *Sirex gigas* perforating sheets of lead. Many years ago, a tin canister was exhibited before the Entomological Society, through which a stag-beetle had gnawed its way, and the marks of its jaws were distinctly visible on the tin.

In his remarks on the bed-bug, which is almost invariably, if not always, apterous, Mr. Butler makes some general observations (p. 287) on the use of wings to insects. It may be mentioned that the late Mr. Wollaston has observed that most insects inhabiting the Atlantic Islands, are either strongly winged, or practically incapable of flight. The explanation which he gives is very curious and interesting. Insects living on small islands exposed to gales are very liable to be blown out to sea. Hence it is almost equally beneficial to them either to be gifted with such strong powers of flight that they can make their way back, in case of such an emergency, or else that they should never fly at all, and thus never run the risk of being blown away.

There are many interesting subjects touched upon in Mr. Butler's work, and much that would admit of further comment; but we have perhaps said enough to indicate its general scope and character. Should it reach a second edition, we think it might be made a little more comprehensive with advantage; for the subject is a very large one, and those who feel a real interest in it rarely find a book too long or too much detailed.

OUR BOOK SHELF.

Text-book of Biology. By H. G. Wells, B.Sc.Lond., F.Z.S., Lecturer in Biology at University Tutorial College. With an Introduction by G. B. Howes, F.L.S., F.Z.S., Assistant Professor of Zoology, Royal College of Science, London. Part II. Invertebrates and Plants. (London: W. B. Clive, University Correspondence College Press, 1893.)

In dealing with a small number of Vertebrate types in Part I. of this book (see Nature, vol. xlvii. 1893, p. 605), the author showed distinct capability and promise; but we feel that he would have done well to wait and work for a few years before publishing this second volume, which covers a larger field. As the types of plants and invertebrates treated of have already been described in so many text-books, the writer had, at any rate, the opportunity of getting his facts and deductions second hand and fairly correctly stated, even without an extensive acquaintance with biological science. There is, therefore, all the less excuse for the many errors and misstatements which occur in this volume, the preface to which would lead one to expect better things in this respect, as well as in the selection and arrangement of facts. Prof. Howes's introduction appeared in Part I.; and before inserting his name on the title-page of Part II. it would, we think, have been only just to have at least submitted the proofs to him. The book would certainly have gained by so doing.

Apart from the more serious faults, which are so numerous that it is not easy to give a short selection of them, awkward terms and misprints abound. Prof. Goebel would probably be surprised to hear that he had written a text-book on botanical "mythology" (p. 94)!

The illustrations are exceedingly crude, and are mostly rough copies of well-known figures. It is, however, only fair to state that the author has purposely made them "as simple and diagrammatic as possible." W.N.P.

The New Technical Educator. Vol. ii. (London, Paris, and Melbourne: Cassell and Co., Ltd., 1893.)

In a notice of vol. i. of this useful work we pointed out that it filled a want in our general technical literature, and that its contents were of a high order. The present volume is quite equal to its predecessor in this respect, and forms a continuation of all the subjects treated in the previous volume.

Under the heading of the "Steam Engine" we find an admirable series of chapters, by Mr. Archibald Sharp, on the subject of valve gear generally, particularly the diagrammatical treatment of the subject illustrative of the various movements of eccentrics, piston and valve. "Electrical Engineering" is also in good hands, being clearly treated by Mr. Edward A. O'Keefe. The many explanations and descriptions given are of a high order of merit. On the subject of "Cutting Tools" much useful information is to be found from the pen of Prof. R. H. Smith, who is an authority on this particular subject. The other subjects embraced in the volume, including practical mechanics, plumbing, photography, steel and iron, drawing for engineers and carpentry, are all well written and illustrated, forming a very useful collection of articles on technical subjects. It is to be regretted, however, that the various articles on different subjects continue in this volume to be mixed together, thus causing the reading of one subject to be a matter of frequent reference to the page of contents.

Heat, and the Principles of Thermodynamics. By Dr. C. H. Draper. (London: Blackie and Son, 1893.)

In these days of innumerable books, it is often a difficult task to correctly appraise the value of a new work, and this is especially the case with books intended for use in classes. The only thing a reviewer can do is to judge whether the volume under his notice differs much from previous volumes on the same subject; and if the author shows no originality of treatment, it seems to us that his book could very well have been left unwritten. Viewing Dr. Draper's work in this light, we find as follows: (1) Much more attention is paid to the principles of thermodynamics than is usual in class-books of its kind; (2) the examples and exercises distributed throughout the book, and at the end, are more numerous than in most text-books of heat, and cover a wider range of examinations; (3) the mathematical section of the subject has not been shirked. Little more can be said. The book is as good as any of its class, and to the student who desires to read up for an examination in heat it should be very helpful.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Systematic Nomenclature.

With reference to Prof. Newcomb's suggested nomenclature for radiant energy, which appeared in Nature, November 30, p. 100, it seems advisable to be rather cautious in adopting new words, or rather terminations to words already more or less in use, for at the present time the student beginning the study of physical science is fairly bewildered with the various forms of words used under the present system, or rather want of system, in nomenclature.

If once for all some system of termination was settled upon

(as in chemistry, for the increasing oxidation results, &c.), the coinage of words as fresh needs arose would proceed automatically on rational lines.

This might very well form the object of a special committee of the British Association.

Mr. Oliver Heaviside's system for electromagnetic matters has much to recommend itself for adoption, also, in general physics.

For example, after the plan (1) conduc*tion*, (2) conduc*tance*, (3) conduc*tivity*, we would have, in the case of radiant energy, (1) radia*tion*, (2) radia*tance*, (3) radia*tivity*.

The first is for reference in a general way to the phenomenon in question; the second refers to its amount in appropriate units in any individual case; while the third is suitable for expressing the peculiar action or factor in the phenomenon possessed by different *kinds* of bodies. Thus the radia*tance* from a hot kettle would be the total quantity of energy lost per second. The radia*tivity* would be the quantity of this per square centimetre.

With a view of examining the feasibility of this system, the following list is subjoined. Many of the words appear at first as if they would prove most awkward in practice, but remembering similar fears (which subsequently proved groundless) in electromagnetic matters, one is afraid to say they are due to more than unfamiliarity.

Phenomenon	Amount of	Coefficient of
Absorption	Absorbance	Absorbivity
Attrition	Attritance	Attritivity
Diffusion	Diffusance	Diffusivity
Emission	Emissance	Emissivity
Expansion	Expansance	Expansivity
Extension	Extensance	Extensivity
Friction	Frictance	Frictivity
Gravitation	Gravitance	Gravitivity
Heat	Heatance	Heativity
Inertia	Inertance	Inertivity
Polarization	Polarizance	Polarizivity
Reflection	Reflectance	Reflectivity
Refraction	Refractance	Refractivity
Rotation	Rotatance	Rotativity
Solution	Solutance	Solutivity

Special attention deserves to be called to inertance as a good name for mass, and inertivity for density, to rotatance for moment of momentum, and rotativity for moment of inertia.

On the Nomenclature for Radiant Energy.

IN connection with this subject there are many things to be considered, and one of the most important is the question of radiation and absorption, which requires a completely new nomenclature to get over very serious ambiguities that at present embarrass the subject. It is very necessary to distinguish between what may be called, on Prevost's theory of exchanges, the total radiatance from the actually observed loss of energy by radiation which is, according to this theory, the difference between the total radiatance and the total absorbance. This difference per degree of temperature is very commonly called the radiating power, but this same word is used in quite a different sense when it is attempted to prove, from Prevost's theory of exchanges, that the radiating is equal to the absorbing powers by a consideration of thermal equilibrium. In this latter case the term radiating power means obviously the total radiatance of Prevost's theory.

It may also be worth while calling attention to the theory, given at Nottingham by Lord Rayleigh, as to the absorbivity of rough surfaces being equal to unity. The general idea underlying his investigation is that owing to diffraction the waves amongst the deep corrugations in the surface spread abroad within them, and hardly any of their energy escapes out again. At the time I called his attention to the way a similar theory would explain the radiating power of rough surfaces, as I have taught here for years back. I am mentioning this now to call attention to an experiment of Magnus' mentioned in Jamin ("Cours de Physique," vol. iii. part 3, p. 113, top line, edition 1881; *Pogg. Ann.* vol. cxxiv. p. 476), where I have an old note concerning this theory, and which I had forgotten, to the effect that the radiation from platinised platinum was much greater than that from smooth platinum, but that the increase was chiefly in the ultra-red rays, for that the difference between the two plates was almost completely annulled by a plate of alum. This is what would be expected from the above theory, because corrugations that are small enough to affect the ultra-red radiations might still be too large to be anything but a smooth surface for the visible radiations. There is evidently a good deal still to be done on radiativity.

Flame.

I TRUST that, in common with other readers of NATURE, I feel duly chastened by the homily which Dr. Armstrong has addressed to you on the subject of my lecture on "Flame." It is perhaps well that we should be warned from time to time against the sin of dogmatising. The only objection I have to the process is that I should be singled out as a sinner without some good reason being given for the selection. I am charged with forgetting that certain alleged facts "are but phenomena interpreted by our own limited intelligence," and yet I actually wound up my lecture with a quotation from Carlyle, intended to emphasise that very point. If Dr. Armstrong had said that *this* was an "appeal to the gallery," I should not have complained.

I do not feel equal to the metaphysical discussion to which Dr. Armstrong opens the way. I know only of one kind of fact, namely, "phenomena interpreted by our own limited intelligence," and it seems better to spell the thing in four letters than to bury it in phrases that smack of the pulpit.

Now let us see what I have done. I found on burning a hydrocarbon with a limited supply of oxygen, that in the cooled products of combustion all the carbon was oxidised, and that some of the hydrogen was set free. I had been brought up, like Dr. Armstrong, to cherish certain chemical dogmas, one of which was that the hydrogen of a burning hydrocarbon was oxidised before the carbon. I now asked myself what were the grounds for this dogma? It seemed to me to spring from the narrowest view of things, probably from the fact—I mean the by-limited-intelligence-interpreted-phenomenon—that hydrogen gas is easier to set on fire than a lump of charcoal. This was obviously an unscientific conclusion, for the carbon of a burning hydrocarbon is part of a gas, and when it is oxidised it has not, like a lump of charcoal, to be virtually gasified in the act of burning, and so to demand a high temperature and an untold amount of heat. I then read with great profit a paper by Dr. Armstrong, which confirmed my opinion that the heat of combustion of an atom of gaseous carbon, in forming carbon monoxide, must be exceedingly high, and so on all grounds I concluded that there was no *prima facie* reason for assuming that the hydrogen of a hydrocarbon would be oxidised in preference to the carbon. Experiment showed the opposite result; the carbon was oxidised, and I adopted the straightforward explanation, and renounced the old dogma. There were alternative explanations. It was conceivable that the hydrogen burnt first and liberated the carbon, which then acted upon the steam to produce one or both of the oxides of carbon and free hydrogen. We should then have two successive chemical reactions. I pointed out that there was only one piece of indirect evidence in favour of this view, and that has since been contradicted by Prof. Dixon. But Dr. Armstrong appears to suggest the view that the two chemical reactions are simultaneous. Now we know of plenty of chemical reactions which are best understood and remembered if we represent them by two simultaneous equations. When, for instance, zinc is heated with strong sulphuric acid, and we do not get hydrogen, we may explain the apparent anomaly by saying that hydrogen *is* liberated, but that it immediately attacks some of the hot sulphuric acid, producing sulphur dioxide and water. Or we may choose another pair of "normal" reactions which, being supposed to happen simultaneously, will explain the "abnormal" result. But surely no one thinks that the two reactions do proceed simultaneously. I use this method of exposition very largely, but I always tell my students that it is analogous to the treatment of forces in dynamics. We suppose

a body acted upon by two forces whose direction and intensity may be conveniently represented by the adjacent sides of a parallelogram. The body *really* moves along the diagonal; *virtually* it has a double track, one along each of the adjacent sides of the parallelogram. In like manner, in our hydrocarbon-oxygen system, we may picture two compelling forces, viz. the tendency of oxygen to combine with carbon, and of oxygen to unite with hydrogen. You may, if you please (and this seems a fascinating exercise to Dr. Armstrong), shut your eyes alternately to each force and say, "first the hydrogen gets all the oxygen, and then the carbon snatches some from it," or you may just as well put it the other way about. I simply recorded the fact that the carbon got the most of the oxygen, with an explicit reference to the fact that I was dealing with the cooled products. Before my experiments were published Dr. Armstrong thought that hydrogen got most of the oxygen. He had actually tried to persuade Sir G. G. Stokes and many others to this effect. When my paper appeared he sought to discount the *facts* it contained by flights of polysyllables worthy of a great statesman.[1] Is it not strange that he should now turn to rend the man who relieved him from what he so abhors—a dogma?

The assumption that the products which are collected from a flame may have totally altered in kind during a minute fraction of a second is perfectly gratuitous, and a similar assumption might be made about nearly every reaction in chemistry. Dr. Armstrong might just as well forbid me to say that zinc and hot sulphuric acid give sulphur dioxide, as to say that when a hydrocarbon burns with limited oxygen, the carbon has the preference.

I will not trespass on your space with a discussion of the liberation of carbon in luminous flames. Dr. Armstrong's contentions on that matter are of precisely the same character as those I have dealt with above. Dr. Frankland has promised us some new evidence in favour of his theory. I trust I have always treated this theory with respect. I am not bigoted on the subject, though I await Dr. Frankland's promised publication with the same sort of feelings as those with which a Neapolitan might look forward to the reawakening of Vesuvius.

I have now, I hope, given an adequate reply to the question of scientific fact raised by Dr. Armstrong. I will not say much about the imputations he casts upon my scientific honesty. It ought not to be a light thing for a man in Dr. Armstrong's position to accuse a scientific worker of deluding an audience into unsound opinions by means of dazzling experiments, of playing to the gallery; of doing, in short, just those things which are most repugnant to the conscience of an earnest investigator. After years of personal friendship, I know Dr. Armstrong's idiosyncrasies very well, and they are, I imagine, pretty well known to the scientific world in general. I feel compelled, none the less, to ask him either to justify or withdraw his aspersions. I make no appeal *ad misericordiam*, and seek no comforting eulogy. It is a duty Dr. Armstrong owes no less to the scientific world than to myself to state clearly and precisely how I have departed from the standards of diffidence, deliberation, and exactitude that are becoming to a man who is honestly seeking to expound the truth. This, at any rate, is a matter the settlement of which is not contingent upon the arrival of that chemical millennium when we shall recognise "chemical interchange and electrolysis as interchangeable equivalent terms"; and I have the right to ask for an immediate and definite reply to my demand.

ARTHUR SMITHELLS.

December 2.

[1] Here is a quotation from one of his letters to Sir G. G. Stokes: "Regarding the interactions in flames as consisting in a series of simultaneous and consecutive explosions, of which we can only examine the final steady state, it seems to me that the phenomena are necessarily of an excessively complex character, and that their appreciation and successful interpretation must tax our powers of mental analysis in a high degree. It will certainly be unwise at present to infer that the oxidation of the hydrocarbons, or the separation of carbon and also of hydrogen from them, takes place entirely in any one way." This seems to me like saying of a fall downstairs, that it is "a series of simultaneous and consecutive" bumps, &c. so difficult to trace out and presenting so many possible varieties of motion that it is hardly safe to call it a fall *down* stairs at all.

The Second Law of Thermodynamics.

CLAUSIUS' supposed deduction of the second law from the ordinary equations of dynamics in the form

$$\frac{\partial Q}{T} = 2\partial \log (iT)$$

has been discussed at length by Messrs. Larmor and Bryan in their Report on Thermodynamics for the British Association. They accept the deduction on condition that the system be conservative, that is, that the external as well as the internal forces acting on it are to be derived from a potential.

Now it is admitted that the equation

$$\frac{\partial Q}{T} = 2\partial \log (iT)$$

can be proved for a conservative system with the meaning of i given in the report. But in order that this equation, however true, may express the second law, T and i must be *independent variables*, or (which is the same thing when there is only one controllable coordinate v) T and v must be *independent variables.*

Now the second law implies comparison of two states, in either of which a substance can exist permanently. So if we seek to prove the law, or an analogous law, for a dynamical system, it is essential that we should compare two states of the system in either of which it is in *stationary motion.* One state may have the variables T and v, and the other may have $T + \partial T$ and $v + \partial v$, but there must be *stationary motion* with either pair of values. If then K be the virial of all the forces, external as well as internal, the Clausian equation, $K = 2T$ must hold. But if the system be conservative, as Larmor and Bryan assume, K is a determinate function of v, and the virial equation constitutes a relation between T and v, so that only one of them is independent. For example, a fixed quantity of gas in equilibrium in a vertical cylinder under a piston of mass "m" acted on by gravity. Clearly if T be given, v, the volume, is determinate, or we have only one independent variable. If m be disposable, you may make T and v vary independently, but then the system is not conservative. It seems to me that Larmor and Bryan's equation does not express the second Law.

Prof. J. J. Thomson, in his "Application of Dynamics to Physics and Chemistry," pages 95–100, proves the second law on a certain assumption. And Boltzmann, "Uber die Mechanischen Analogien des zweiten Hauptsatzes," has proved it on, I think, the same assumption. In order to show clearly the nature of the assumption I will begin a proof as follows, treating only the case of T temperature, and v volume. If χ denote the potential of all the conservative forces, p the external force necessary to maintain v constant, we have T being the mean kinetic energy of one of N molecules

$$\partial Q = N\partial T + \partial\bar{\chi} + p\partial v.$$

But by the virial equation

$$p\partial v = \tfrac{2}{3}NT\frac{\partial v}{v} - \overline{\frac{d\chi}{dv}}\partial v,$$

in which $\overline{\frac{d\chi}{dv}}$ is to be distinguished from $\frac{d}{dv}\bar{\chi}$ as explained in Watson's "Kinetic Theory of Gases."

Therefore

$$\partial Q = N\partial T + \tfrac{2}{3}NT\partial \log v + \partial\bar{\chi} - \overline{\frac{d\chi}{dv}}\partial v,$$

or

$$\frac{\partial Q}{T} = N\partial \log T + \tfrac{2}{3}N\partial \log v + \frac{1}{T}\left(\partial\bar{\chi} - \overline{\frac{d\chi}{dv}}dv\right),$$

now make

$$i = \frac{v^{\frac{1}{3}}}{T^{\frac{1}{2}}}$$

(a definite time), then

$$\partial \log T + \tfrac{2}{3}\partial \log v = 2\partial \log (iT),$$

and therefore

$$\frac{\partial Q}{T} = 2N\partial \log (iT) + \frac{1}{T}\left(\partial\bar{\chi} - \overline{\frac{d\chi}{dv}}\partial v\right).$$

Now J. J. Thomson assumes (p. 97) that $\bar{\chi}$, in his notation V, is to be a function of v only, whence it follows that

$$\partial\bar{\chi} - \overline{\frac{d\chi}{dv}}\partial v = 0,$$

as he says, and so

$$\frac{\partial Q}{T} = 2N\partial \log(iT),$$

which I submit as a form of his result (118). I understand Boltzmann in the treatise above cited to make the same

assumption. J. J. Thomson subsequently considers the case of χ being a function of T as well as of v (p. 100). But he does not in this case make $\frac{\partial Q}{T}$ a complete differential.

I think that in the general case we must regard χ as a function of the unconstrainable coordinates, and as varying from one configuration to another, through which the system passes in the same stationary motion with constant v. When v becomes $v + \partial v$ we do work in two ways. Firstly, we alter the value of χ for each configuration, doing thereby on the whole an amount of work equal to $\frac{d\chi}{dv}\partial v$. Secondly, we alter the comparative frequency of different values of χ in the stationary motion. This is essential; for without this the system would not be in stationary motion with the altered values of T and v. I think J. J. Thomson had this in his mind when he made χ a function of T as well as v (p. 100).

Let, then, $f dx_1 \dots dx_n$ or $f d\sigma$ denote the frequency of the configuration $x_1 \dots x_n$, so that

$$\bar{\chi} = \int f\chi d\sigma, \quad \overline{\frac{d\chi}{dv}} = \int f\frac{d\chi}{dv}d\sigma,$$

and

$$\partial\bar{\chi} = \int f\partial\chi d\sigma + \int \chi\partial(fd\sigma)$$

$\partial d\sigma$ referring to variation of the limits of integration

$$= \int \chi\partial(fd\sigma) + \overline{\frac{d\chi}{dv}}dv.$$

and so

$$\partial\bar{\chi} - \overline{\frac{d\chi}{dv}}\partial v = \int \chi\partial(fd\sigma)$$

and

$$\frac{\partial Q}{T} = 2N\partial \log(iT) + \frac{1}{T}\int \chi\partial(fd\sigma).$$

Now how to make

$$\frac{1}{T}\int \chi\partial(fd\sigma),$$

or

$$\int \frac{\chi}{T}\partial(fd\sigma),$$

a complete differential?

If

$$B = \int f(\log f - 1)d\sigma$$

(Boltzmann's minimum function),

$$\int \log f\partial(fd\sigma) = \partial B + N\partial \log v,$$

and is a complete differential.

Hence one solution, and probably the only general solution, of the problem is obtained by making log Cf proportional to $\frac{\chi}{T}$, or

$$f = C\epsilon^{-c\frac{\chi}{T}},$$

where c is numerical. That gives

$$\frac{\partial Q}{T} = 2N\partial \log(iT) - \frac{1}{c}\partial B - \frac{N}{c}\partial \log v.$$

Since $2iT$ is the Action of the system during the definite time i, we see that the second law stands in a certain relation to the principle of least Action. But I think the complete treatment of it must be based on the virial equation. And it may be regarded as the law of the variation of B when T and the controllable coordinates vary.

S. H. BURBURY.

THE LOSS OF H.M.S. "VICTORIA."[1]

III.

LAST week we discussed the opinions expressed by the Board of Admiralty, in their Minute of the 30th of October, upon certain points that relate to the construction and stability of the *Victoria;* but the remainder was left for consideration in the present concluding article.

The value of an armour-belt at the ends for resisting damage.—Their lordships say "the fact that the *Victoria* was not armour-belted to the bow had no influence upon the final result of the collision. No armour-belt could have prevented the ripping open of the bottom below water by the ram-bow of the *Camperdown*, and the flooding of the compartments to which water could find access through the breach." Mr. White argues strongly against the assertion, which he states has been made, that if a strong armour-belt had existed at the place where the blow was struck, the damage might have been greatly reduced and the ship kept afloat. He considers that all the most important compartments which were flooded in the *Victoria* must have been thrown open to the sea under the conditions of the collision, even if there had been such a belt. "The breach in the side might have been different in form and possibly less extensive, especially above water; but it must in any case have been of large extent, and have admitted very large quantities of water in a short time." Mr. White proceeds to argue that the extent to which the *Camperdown* penetrated into the interior of the *Victoria* was not altogether a disadvantage, as the *Camperdown's* bow thus became virtually locked in the protective deck of the *Victoria*, till the relative forward movement of the latter ship was destroyed and the tearing action of her spur upon the side of the *Victoria* was thereby prevented. "Under the assumed condition of a non-penetrable armour-belt, this relative forward movement and tearing action must have taken place." But the Admiralty cannot admit the assumption of impenetrability. Reference is made to cases of collision, such as those between *Vanguard* and *Iron Duke*, and between *Grosser Kurfürst* and *Konig Wilhelm*, which prove, in Mr. White's opinion, that "the existence of an armour-belt is no sufficient safeguard against injuries resulting from serious collision."

The objections that have been made to leaving so much of the ends of some of our first-class battleships unprotected by armour, have been mainly in connection with their defence against gun-fire. The gun is, and appears likely for some time to be, the weapon of attack which a battleship must be designed primarily to resist. The attack of the ram can often be evaded by speed or skilful handling; and that of the torpedo by watchfulness, tactical resource, and smart conduct on the part of the officers in command. The real defence against rams and torpedoes lies at present much more in the judgment and skill with which a ship can be safeguarded or manœuvred by her officers, than in her own intrinsic power of resistance.

At the same time, it is obviously desirable that everything possible should be done to increase the amount of resistance that can be offered by a ship's hull to attack from ram or torpedo. The Admiralty say that an armour-belt would have no influence upon the final result of ramming. This statement is based upon two assumptions: (1) that "under a blow of such energy as was delivered on the *Victoria* the strongest armoured side ever constructed must have yielded and been driven in. Its water-tightness and that of the bulkheads, &c., within it adjacent to the place where the blow was struck, must have been destroyed, and the ultimate result (as regards the admission of water) would have been practically as serious under the same conditions of open water-tight doors, &c. as that which actually occurred in the *Victoria*"; and (2) that if the *Camperdown's* bow had been prevented by an armour-belt from penetrating to so great a depth as was stated into the side of the *Victoria*, her spur would have torn away much more of the bottom plating than it actually did.

The truth of both these assumptions appears very

[1] Continued from p. 127.

questionable. With regard to the first, it is pointed out that the ram-bow of the *Iron Duke* drove the armour of the *Vanguard* bodily inwards more than a foot. The armour of the *Vanguard* was, however, only 6 to 8 inches thick, while the force of the blow with which she was struck is said to have been two-thirds of that delivered to the *Victoria*. The armour at the point where the *Victoria* was struck would have been 15 or 16 inches thick if she had been fitted with an armour-belt, while the energy of the blow delivered to her is stated to have been "about the muzzle energy of a 12-inch 45-ton B.L.R. gun, the estimated perforation of its projectile being about 22½ inches of wrought-iron armour." The armour of the *Victoria* was not, however, of wrought iron, but of iron faced with steel, on the "compound" principle, which offers much greater resistance to penetration than wrought iron.

Seeing that the depth of the armour-belt would be 7 to 8 feet, and its thickness 15 or 16 inches: and that the projectile referred to, whose energy is about equal to that of the blow delivered to the *Victoria*, only succeeds in penetrating the plate by concentrating its whole effect upon an area 12 inches in diameter, it does not appear that the armour ought to suffer much from a blow distributed over so much greater an area. The armour of the *Vanguard* was driven in because the supports in its rear were not strong enough to resist the blow. In our present ships the top of the armour-belt comes against the edge of a protective deck, which is 2½ or 3 inches thick, and could well be supported and connected to it in such a manner as to effectually resist being driven inwards; and it appears to be mainly a question of fitting a similar bearing at the bottom of the armour, in connection with the armour-shelf, to furnish sufficient resistance at the lower edge. Such an arrangement for supporting the armour would not be difficult to devise; and it does not appear impossible to thus construct an armour-belt, in a ship like the *Victoria*, that would resist being driven in by such a blow as she received; and would do so without necessarily causing the water-tightness of the bulkheads, &c. adjacent to the place where the blow was struck, to be destroyed by the shock of the collision. The fact is that armour-belts have usually been arranged exclusively for keeping out projectiles from guns, and not with the view of resisting ramming. Had the latter been regarded as an important function for armour-plating to perform, the lower edge of armour, which would receive the first force of the blow in many cases, would have been supported in the rear better than it now is, and probably somewhat in the manner indicated.

The second assumption upon which the opinion that an armour-belt would have been useless is based is that, by preventing the *Camperdown* from penetrating so far as she did into the interior of the *Victoria*, there would have been serious tearing of the bottom abaft the breach as the ships got clear of each other. In support of this it is stated that the bow of the *Konig Wilhelm* tore open the bottom of the *Grosser Kurfürst* for some distance abaft the first breach, owing to the speed with which the latter vessel tried to cross ahead of her. This tearing action would depend very much, however, upon whether the point of the ram would have penetrated far enough into the bottom below the armour-belt to keep the ships together for a sufficient time, and it is quite likely that it would. Anyhow, it is impossible to say what depth of penetration would be necessary for this purpose, especially as the ram bows of ships by which a British vessel might be attacked are very different in length and form; and it seems a doubtful process of reasoning which leads to the result that the great depth to which the side of the *Victoria* was penetrated might not have been considerably reduced with advantage.

But the objections that have been made to leaving so great a length at the ends of a battleship without armour are not, as we have said, with reference to their being rammed, but because of the damage to which they are thus exposed by gun-fire. The results of the Admiralty calculations show that the effect of gun-fire upon the unarmoured ends of such ships as the *Victoria* might be very serious. We are informed by Mr. White that the *Victoria*, as she was at the time of the collision, would change her trim 3 feet by the bow in consequence of 110 tons loss of buoyancy above the protective deck. It follows, therefore, that if the whole of the compartments above the protective deck were penetrated so as to admit water, there would be a loss of buoyancy sufficient to change her trim fully 5 feet by the head. The change of trim and extra mean immersion thus caused by the loss of buoyancy would bring the top of the armour-belt close to the water-line at its fore end; and the slightest inclination would then be sufficient to immerse the fore end of the armour-belt on its inclined side. Perforation of the thin side plating at this point above the armour would thus admit water into the ship over the top of the armour-belt, and lead to a growing loss of buoyancy and stability, both transverse and longitudinal, which would soon place the vessel in a perilous position. The destruction of such a ship does not thus appear very difficult by the large rapid-firing guns that are carried in cruisers and in the secondary batteries of battleships. These guns, firing twelve to twenty projectiles of 6 inches and 4¾ inches diameter, per minute could be aimed with great precision at the water-line of a ship, and would very soon cause the whole of the thin partitions in the unarmoured ends to be penetrated through and through, and admit water freely into the whole of the compartments. If the vessel thus attacked were steaming ahead, at the slowest speed possible, the additional water that would thus be forced in would greatly increase the change of trim, and it would only be necessary to follow up the process of aiming at the water-line along the fore end, and over the top, of the armour-belt in order to soon disable or sink her.

The foregoing considerations may suffice to show that we see no sufficient grounds for believing the Admiralty to be right in the assertion that the absence of an armour-belt at the bow had no influence upon the final result of the collision in the case of the *Victoria*; still less that an armour-belt could not be made more effective than it now is against the attack of a ram; and still less, again, that an armour-belt of sufficient length to furnish all the buoyancy and stability necessary for safety would not afford a most powerful protection to a battleship against the destructive effects of the present rapid gun-fire.

The sufficiency of the stability possessed by the ship.—The Admiralty say "the capsizing of the *Victoria*, under the special circumstances described, does not suggest any insufficiency of stability in the design of that vessel. The provision made was ample for all requirements. When fully laden and in sea-going trim the metacentric height was 5 feet, stability reached its maximum at an angle of 34½ degrees to the vertical, and the range of stability was 67½ degrees." It will be observed that it is only the stability that would be possessed when the hull of the ship is absolutely intact that is here spoken of; and it is doubtless sufficient for that condition, and would enable the vessel to take considerable quantities of water on board without danger. This is not a point, however, which has great practical importance in connection with actual fighting requirements. In order to judge of the sufficiency of the stability under ordinary fighting conditions it is necessary to know what it would be when the thinly-plated ends and compartments outside the armour-belt are penetrated by projectiles. This is a

factor of such great importance to the problem, as to make the bare information with regard to the stability in the intact condition comparatively valueless. Whether the provision of stability was ample, in the *Victoria*, for all requirements, as the Admiralty assert, or is ample in existing ships of similar type, depends almost entirely, as regards the fighting requirements of a first-class battleship, upon what it is when the thinly-plated ends are penetrated. It is quite certain that damage to the ends would soon make demands upon the stability, which necessitate the provision of a large reserve in the intact condition for drawing upon, and that this reserve should be sufficient to cover not merely the heeling effect of water held over to one side by longitudinal partitions, but also the reduction of stability due to loss of buoyancy in compartments that are opened up to the sea, and the effect of speed of ship upon the quantity of water that might be admitted, and the position into which it might be forced. There is no necessity to look far in order to see that the stability could thus be seriously reduced very early in an action, and might soon become insufficient to enable the ship to be handled and fought as she should be, if not to place her in absolute peril.

The steps that should be taken "to prevent the recurrence, under similar circumstances, of the conditions which, after the collision, resulted in the loss of the ship."—The Admiralty considers that the only step requisite is to issue regulations to the fleet which will ensure "that, under special circumstances, and particularly when there is risk of collision, doors, hatches, &c. shall be kept closed as far as possible, and men stationed at any that are necessarily left open"; also, "that under certain conditions arising out of collision or under-water attack, the gun-ports and other openings in the upper structure shall be closed before water can enter and endanger the stability of the ship." Now, everyone acquainted with the Admiralty and the Navy must know perfectly well that this really leaves matters as they were. Officers in command of H.M. ships are quite aware that water-tight doors, hatches, &c. require to be worked in the manner described; but the difficulty is to do it, in any emergency that may arise, so as to be effective for the purpose. The great number of water-tight doors, the difficulty of properly securing some of them, and the necessity that exists for many to be frequently open in order to carry on the ordinary work of the ship, makes it practically impossible to ensure that safety can always be relied upon by such precautions. It is true that the *Victoria* would, in all probability, not have been lost if all the water-tight doors and hatches in the fore part of the vessel had been closed; but it does not therefore follow that a similar disaster can be prevented in future merely by an order from the Admiralty directing that all such doors, &c. are to be closed in future in sufficient time to keep water from passing out of one compartment into another.

We would recommend that the number of water-tight doors in the various compartments be reduced; that no door which is essential to efficient water-tight sub-division, and is ever required to be left open without attendance, be fastened merely by clips; that all doors which are relied upon for safety should be capable of being closed either by a satisfactory self-acting arrangement, or by appliances for working them from a deck at a safe height above water. We would also call attention to the danger of making the safety of a ship depend upon the complete closing of a large number of small compartments. The only arrangement that can be relied upon is one of subdivision into a series of main compartments, formed by bulkheads that are carried to a deck that is high above the water-line, which will be perforated as little as possible by doors, or by pipes, &c. below water. Such an arrangement as that in the *Victoria*, where the efficiency of some of the divisional bulkheads, which appear to have formed part of the system of water-tight subdivision, depended upon the closing of scuttles in a water-tight deck only 3 feet above water, at which the bulkheads stopped, is manifestly untrustworthy; and it is impossible for the Admiralty to remedy its defects by promulgating orders to make it work.

So far as other ships of the type of the *Victoria* are concerned, the Admiralty does not see that the necessity for any improvement is indicated. We consider, however, as the foregoing remarks show, that the result of the ramming of the *Victoria* points clearly to the necessity of making the armour-belts longer in such ships if the armour is to be made really effective. This would increase the power of resistance to gun-fire, while the belts might be so fitted as to reduce the injuries likely to be caused by ramming. Water-tight flats at a small height above water, and thin bulkheads above water, are of little good against rapid gun-fire. Vessels with short armour-belts, such as the *Victoria* and others of her type, might, as has been pointed out, be destroyed by rapid gun-fire without any penetration of their armour; so that their defensive power is not measured by the resistance to penetration of the armour they carry. They thus belong more to the type that are called protected ships than to that of armour-clads; and it would probably be more correct to classify them as such. Their names now figure in the list of first-class battleships, and make our Navy appear stronger in this class of ships than it really is. If they were classed according to their real fighting value, the necessity for adding to the number of battleships would appear stronger than it now does to those who cannot judge the relative merits of ships.

Another lesson taught by the *Victoria* disaster appears to be that the officers of such ships should be more fully instructed with regard to the probable effects of various kinds of injury than they now appear to be. It is quite certain that the officers of the *Victoria* never imagined that the ship could sink so rapidly as she did, even with many of the water-tight doors open, or that her safety depended, to the extent it did, upon the absolute closing of so many small compartments. They require to be advised, and to obtain some experience as to the best mode of treatment under different conditions of damage. Would the captains of the ships with short armour-belts all know, for instance, whether it would be better or not to admit water into the ends before going into action? Has it been decided that it would be better to thus admit water, and prevent changes of trim as the thin ends become perforated by projectiles, or to keep water out as long as possible, and to submit to changes of trim and of heeling to one side or the other as the various compartments were opened up? The effect of loose water in the ends might be very objectionable if the speed of the ship were changing, or if she were rolling to any extent; but it would exist as soon as the ends became damaged; and it is clear that the presence of a large body of water in the long unarmoured ends of some of these ships would be a great source of difficulty in keeping speed and in manœuvring.

The general result of the Admiralty investigation, and of the judgment based upon it, is that there is no fault to be found with any single point connected with the construction and arrangements of the *Victoria*, or other ships of her type, for which those who conducted the investigations, or pronounce the judgment, could be held responsible; but that the whole blame is due to the one cause with which no one at the Admiralty could be in any way connected, viz. the failure to close all the water-tight doors, hatches, &c. in time to prevent the disaster. In saying this we do not wish to cast any doubt upon the accuracy of the calculations which have been made, or upon the desire of the Admiralty to arrive

at a fair decision upon the questions raised. It is impossible for persons who are deeply interested in these questions, and in the results of the investigation, to divest themselves of all feeling and bias, and to judge their own ideas and work from an absolutely impartial standpoint. It would probably happen in any inquiry, that if one of the parties implicated were allowed to draw up the judgment, the result would not be unfavourable to itself. Most people appear satisfied, however, that this course should be taken when the question involved is that of the efficiency of the battleships upon which the defence of the British Empire would mainly depend in the event of war.

Francis Elgar.

THE NEW LABORATORIES OF THE INSTITUTE OF CHEMISTRY.

At length the members of the Institute of Chemistry may feel entitled to cry with Proteus, "Time is the nurse and breeder of all good," for now the object, kept steadily in view through evil report and good, though there was mighty little of the latter, has been achieved, and the Institute of Chemistry finds itself in the possession of a house with offices, council chamber, examination rooms, laboratories for examination, and everything handsome about it.

The successive councils are to be congratulated on the firmness with which they have resisted the numerous and persistent attempts which have been made by a somewhat important body of members to force the Institute into becoming a publishing and paper-producing body, thus adding another to the already too numerous chemical journals.

The Institute was not founded for this purpose; but the fact was forgotten again and again by those who were apparently unable to resist the temptation to spend the gradually accumulating funds of the Institute on "doing something," no matter what, but preferably holding meetings and printing a journal. The councils, however, proved wiser than some of their constituents, and held to the true view of their function, namely, that they were an examining and qualifying body.

Upwards of twenty years ago the passage of the Food and Drugs Act led to a series of appointments of public analysts that taken in the mass were little short of scandalous. The chemical profession had no corporate existence; it had never been consulted in the matter of drafting the Act, and the Government of the day, though having eminent chemists at command, never asked any advice. County and borough, corporation and vestry, were required to appoint "analytical chemists," and, left to their own sweet will in making the selection, with results that can be more easily imagined than described. It was this that literally forced the then small number of men who were practising chemistry professionally, to organise themselves with a view, not of undoing the mischief already done, for that was irreparable, but of gradually supplying a body of men whose qualifications were vouched for by a searching examination.

These examinations, at first held in town and at a number of provincial centres, have gradually concentrated in London, and the increasing number of examinees at length warned the council that the time had come when the Institute must be able to examine under its own roof.

The presidency of Dr. Tilden has been signalised by the carrying through of this project. After a prolonged search, suitable premises were found at No. 30 Bloomsbury Square, and the lease purchased. The House Committee, consisting of the President and Treasurer, with Prof. J. M. Thomson and Mr. R. J. Friswell, immediately set about planning the laboratory, the architectural work being placed in the hands of Mr. H. V. Lanchester.

The immediately surrounding property being residential, it was of great importance to prevent any nuisance from the escape of fumes, and the committee, in view of the almost universal failure of most of the fume apparatus in existing laboratories, placed themselves in the hands of one of their members whose experience as a chemical manufacturer led him to adopt the novel expedient of treating the laboratory as an acid factory, and scrubbing and burning the fumes, the latter by means of a specially constructed furnace, which also causes the draught by which the fumes are removed. So far this arrangement appears to work well, and it will no doubt be watched with interest by future builders of laboratories.

When the premises were taken over they consisted of a house of 36 feet frontage and 45 feet depth. Behind this lay a space of 60 feet by 36 feet, partly covered by an old building, once no doubt a stable, and partly occupied by an area and a built-out basement kitchen, which had a very large chimney, built independently of the house chimneys, and about 95 feet high and 18 inches square. The old building being removed, there remained an area of 34 by 36 feet for the principal laboratory, while the basement kitchen could be easily converted into a combustion laboratory, and its tall chimney—a factory shaft on a small scale—utilised for ventilating the fume cupboards and working benches.

The house faces nearly due west, and this permitted the laboratory to be lighted entirely from the north. As it was not possible to erect a lofty roof, it was decided to divide it into three gables, each having one side of glass, the other, turned towards the south, slated and matchboarded inside. These unglazed sides rise at an angle of 40°, and are so prolonged that the glazed sides, rising at an angle of 60°, meet them at an angle of 80, and the entrance of direct sunlight is thus prevented, and, except for a very short time in the middle of the day, at midsummer. The main laboratory, 35 × 32 feet, is fitted with thirty-two working benches, and a desk for the examiner; two fume chambers and one bench of muffles being arranged at each end. It is lined throughout with white glazed bricks, the floor is of 2-inch pitchpine, and the working benches are of the same wood with mahogany edges, and tops saturated with high melting paraffin wax. Each bench has the necessary reagent shelves, seven drawers, and ample space with shelves beneath for the storage of large apparatus. It is also provided with two gas-cocks, a low-pressure water-cock, another for the supply of a condenser, and one high-pressure cock for a Sprengel filter pump. The sinks are circular, of salt-glazed stoneware, and so arranged that each supplies accommodation for four benches. Under each bench, below the floor level, runs an 8-inch Doulton pipe (which gives off 3-inch branches to each bench), and connects with a 12-inch main which runs along the front wall and descends to the level of the combustion laboratory floor, where it enters a salt-glazed stoneware tower packed with coke, and provided with a water shower. Passing up this, which is 2ft. 6in. diameter and 13ft. 6in. high, the washed fume is carried by another 12-inch pipe to the ground level again, and enters the ashpit of a furnace 4ft. × 1ft., which has fire-brick doors closing air-tight against planed cast-iron rims. Separate 8-inch pipes communicating with the 12-inch main go to each fume cupboard, and when the furnace is alight a most powerful draught, amounting to about 12,000 cubic feet of air per hour, is drawn from the benches and fume cupboards.

The stone muffle benches are each provided with a

small flue in the wall, and will accommodate eight full-sized gas muffles. All the gas, water, heating, and fume pipes, together with the drains, which have specially arranged intercepting tanks to prevent the loss of mercury or the carrying of solid matter into the sewers, are carried beneath the benches in an ample stone-paved recess below the floor level. There is an easy means of access to all these pipes by sliding out the bottoms of the apparatus stores, which are arranged below each bench, and protected by an iron foot-rail.

Air from outside is also admitted from the same space, and is thus slightly warmed before entering the laboratory. The glass lights in the roof can, if desired, be opened. Artificial light is provided by six powerful self-ventilating Wenham gas-lamps, but it is hoped in time to provide incandescent electric lights to each bench.

Just outside the laboratory is a balance room fitted with six Oertling balances; this room is small, but the exigencies of the site did not permit of a larger area. Opposite the balance room a spiral staircase enables the examiner in charge to at once descend to the combustion laboratory. This room, 23 × 13, is fitted with seven stone-topped combustion benches, each 4ft. 6in. × 1ft. 3in., provided with a ¾in. fullway gas cock. Behind this is a vault lighted by prism light in the laboratory floor, in which is placed a powerful high-pressure water heating apparatus. Outside in the area is a washing-up room, provided with requisite shelves, sink, &c., and supplied with gas, so that the rougher operations of a laboratory, the handling of carboys, storage of acids and bulky chemicals, &c., can there take place.

From the house the laboratory is entered by a corridor starting from the cloak-room. The latter is large and amply provided with all necessaries, and with it communicates a commodious and well-fitted lavatory, having hot and cold water and all necessary fittings.

Behind the office, a handsome oak-floored room in the house itself will serve as a suitable laboratory for gas analyses.

Besides the accommodation here described, the house contains fifteen large rooms and a fine entrance hall. On the ground floor the front room serves as the office. The first floor supplies two large council and committee rooms, while the basement furnishes the housekeeper with ample accommodation. It will thus be seen that there is plenty of room for expansion.

The proverbial delays of the law prevented the House Committee from getting to work until August had begun. Its members are to be congratulated on the work they have done, and the time, four months, in which it has been accomplished.

The opening of the laboratories took place on Friday, December 8, at one o'clock, when the President received a number of gentlemen, who subsequently inspected the new buildings. The company included Sir F. Abel, F.R.S., Dr. Bell, F.R.S., Dr. H. E. Armstrong, F.R.S., Dr. Russell, F.R.S., Prof. Ramsay, F.R.S., Prof. Hartley, F.R.S., Prof. Clowes, Mr. C. E. Groves, F.R.S., Prof. Meldola, F.R.S., Mr. R. J. Friswell, Mr. O. Hehner, Dr. T. A. Lawson, Mr. D. Howard, Mr. Ernest Hart, and many other gentlemen and representatives of the press. Letters and telegrams regretting absence were received from Sir W. Foster, M.P., Sir H. Roscoe, M.P., Mr. Fowler, M.P., Mr. Norman Lockyer, F.R.S., Prof. J. M. Thomson, the Duke of Bedford, &c.

At half-past one the President delivered a short address dealing with the history and objects of the Institute, which now consists of 731 fellows and 104 associates, and has 200 registered students on its books. On the conclusion of this brief ceremony the laboratories being declared open, the President invited the assembled company to luncheon, which was laid in the council rooms. Sir F. Abel proposed the President's health, to which Dr. Tilden briefly replied, after which the meeting broke up.

SCIENCE IN THE MAGAZINES.

DR. A. R. WALLACE contributes to the *Fortnightly* the second part of his article on "The Ice Age and its Work." He deals in detail with the erosion of lake basins, first describing the different kinds of lakes, and their distribution, and then the conditions that favour the production of lakes by ice-erosion. The objections of modern writers are afterwards considered *seriatim*, and the manner in which they are handled will give pleasure to all glacialists. The alternative theory to that of ice-erosion, for the origin of the class of lakes discussed, viz. that they were formed before the glacial epoch, by earth-movements of the same nature as those concerned in mountain formation, appears to be fairly presented, and the difficulties in the way of accepting it are pointed out. Evidence is adduced to show that the contours and outlines of the lakes in question indicate erosion rather than submergence, and, finally, the Lake of Geneva is taken as a test of the two rival theories. As the subject discussed is very complex, and the argument essentially a cumulative one, Dr. Wallace gives the following summary of the main points:—

In the first place, it has been shown that the valley lakes of highly glaciated districts form a distinct class, which are highly characteristic, if not altogether peculiar, since in none of the mountain ranges of the tropics, or of non-glaciated regions over the whole world, are any similar lakes to be found.

The special conditions favourable to the erosion of lake-basins, and the mode of action of the ice-tool, are then discussed, and it is shown that these conditions have been either overlooked or ignored by the opponents of the theory of ice-erosion.

The objections of modern writers are then considered, and they are shown to be founded either on mistaken ideas as to the mode of erosion by glaciers, or on not taking into account results of glacier-action which they themselves either admit or have not attempted to disprove.

The alternative theory—that earth-movements of various kinds led to the production of lake-basins in all mountain ranges, and that those in glaciated regions were preserved by being filled with ice—is shown to be beset with numerous difficulties, physical, geological, and geographical, which its supporters have not attempted to overcome. It is also pointed out that this theory in no way explains the occurrence of the largest and deepest lakes in the largest river valleys, or in those valleys where there was the greatest concentration of glaciers, a peculiarity of their distribution which points directly and unmistakably to ice-erosion.

A crucial test of the two theories is then suggested, and it is shown that both the sub-aqueous contours of the lake-basins, and the superficial outlines of the lakes, are exactly such as would be produced by ice-erosion, while they could not possibly have been caused by submergence due to any form of earth-movements. It is submitted that we have here a positive criterion, now adduced for the first time, which is absolutely fatal to any theory of submersion.

Lastly, the special case of the Lake of Geneva is discussed, and it is shown that the explanation put forth by the anti-glacialists is wholly unsupported by facts, and is opposed to the known laws of glacier motion.

The *Contemporary* is included among the magazines that we have received, and to it Mr. Herbert Spencer contributes a rejoinder to Prof. Weismann. "As a species of literature," he remarks, "controversy is characterised by a terrible fertility. Each proposition becomes the parent of half-a-dozen, so that a few replies and rejoinders produce an unmanageable population of

issues, old and new, which end in being a nuisance to everybody." If this opinion had come from anyone but one of the debaters it would have been ungracious. The questions at issue between Weismann and Spencer and Romanes have become so involved that some discrimination is required to unravel the tangled skein of argument. Mr. Spencer therefore confines his replies to those arguments of Prof. Weismann which are contained in his first article. The following points are of interest:—

Prof. Weismann says he has disproved the conclusion that degeneration of the little toe has resulted from inheritance of acquired characters. But his reasoning fails against an interpretation he overlooks. A profound modification of the hind-limbs and their appendages must have taken place during the transition from arboreal habits to terrestrial habits; and dwindling of the little toe is an obvious consequence of disuse, at the same time that enlargement of the great toe is an obvious consequence of increased use.

The entire argument based on the unlike forms and instincts presented by castes of social insects is invalidated by an omission. Until probable conclusions are reached respecting the characters which such insects brought with them into the organised social state, no valid inferences can be drawn respecting characters developed during that state.

A further large error of interpretation is involved in the assumption that the different caste-characters are transmitted to them in the eggs laid by the mother insect. While we have evidence that the unlike structures of the sexes are determined by nutrition of the germ before egg-laying, we have evidence that the unlike structures of classes are caused by unlikenesses of nutrition of the larvæ. That these varieties of forms do not result from varieties of germ-plasms is demonstrated by the fact that where there are varieties of germ-plasms, as in varieties of the same species of mammal, no deviations in feeding prevent display of their structural results.

Mr. Spencer also shows that for such caste-modifications as those of the Amazon ants, which are unable to feed themselves, there is a feasible explanation other than that given by Prof. Weismann. With regard to panmixia, he says:—

The tacit challenge I gave to name some facts in support of the hypothesis of panmixia—or even a solitary fact—is passed by. It remains a pure speculation having no basis but Prof. Weismann's "opinion." When from the abstract statement of it we pass to a concrete test, in the case of the whale, we find that it necessitates an unproved and improbable assumption respecting *plus* and *minus* variations; that it ignores the unceasing tendency to reversion; and that it implies an effect out of all proportion to the cause.

It is curious what entirely opposite conclusions men may draw from the same evidence. Prof. Weismann thinks he has shown "that the last bulwark of the Lamarckian principle is untenable." Most readers will hold with me that he is, to use the mildest word, premature in so thinking.

A short article on "Water Bacteriology and Cholera," by Mrs. Percy Frankland, appears in *Longmans' Magazine*. It deals chiefly with the value of sand filtration as a means of purifying water. The report of the cholera epidemic in Hamburg and Altona has strikingly proved that sand-filters offer a remarkable and obstinate barrier to the passage of disease organisms, as well as the ordinary harmless water bacteria. Here is a statement of the facts:—

These two cities are both dependent upon the river Elbe for their water-supply, but whereas in the case of Hamburg the intake is situated *above* the city, the supply for Altona is abstracted below Hamburg *after it has received the sewage of a population of close upon* 800,000 *persons*. The Hamburg water was, therefore, to start with, relatively pure when compared with that destined for the use of Altona. But what was the fate of these two towns as regards cholera? Situated side by side, absolutely contiguous in fact, with nothing in their surroundings or in the nature of their population to especially distinguish them, in the one cholera swept away thousands, whilst in the other the scourge was scarcely felt; in Hamburg the deaths from cholera amounted to 1,250 per 100,000, and in Altona to but 221 per 100,000 of the population. So clearly defined, moreover, was the path pursued by the cholera, that although it pushed from the Hamburg side right up to the boundary line between the two cities, it there stopped, this being so striking that in one street, which for some distance marks the division between these cities, *the Hamburg side was stricken down with cholera, whilst that belonging to Altona remained free.* The remarkable fact was brought to light that in those houses supplied with the Hamburg water cholera was rampant, whilst in those on the Altona side, and furnished with the Altona water, not one case occurred. We have seen that the Hamburg water, to start with, was comparatively pure when compared with the foul liquid abstracted from the Elbe by Altona, but whereas in the one case the water was submitted to exhaustive and careful filtration through sand before delivery, in Hamburg the Elbe water was distributed in its raw condition as drawn from the river.

Also in *Longmans'*, Sir John Evans writes on "The Forgery of Antiquities." From his history of ingenious frauds perpetrated in every branch of archæology we select the following:—

Of prehistoric antiquities, both in stone and bronze, forgeries are numerous, but it seems needless to enter into all the details of their character, and of the means that may be employed to detect their fraudulent origin. Suffice it to say that in the gravel-pits of the valley of the Somme and of the neighbourhood of London the manufacture of palæolithic implements takes rank as one of the fine arts. The chipping of the English forgeries is superior to that of the French, but in each case the lanceolate form is the favourite. The appearance of antiquity is usually given by a thin coating of fine clay, but at Amiens a plan of whitening the flint by long boiling in the family kettle has been introduced. . . . In some of the bone-caves of the Reindeer period, both in France and Germany, ancient bones have had designs engraved upon them by modern forgers, and ancient flint tools have been inserted in sockets of ancient bone so as together to form a composite falsification. Something of the same kind has been practised with regard to relics from the Swiss lake-dwellings, many of the bronze objects from which have also been imitated by casting.

Of neolithic implements forgeries are equally abundant, and in some instances equally difficult to detect. Large perforated axe heads when made of soft sandstone which could not possibly be used for cutting purposes, of course betray themselves; but the modern flint axes and arrowheads are not so easily distinguishable from the ancient. To the experienced eye there is, however, a difference both in the workmanship and the character of the surface, the ancient arrowheads having probably been worked into shape by pressure with a tool of stag's horn, and not by blows of an iron hammer. The grinding of the edges of modern imitations has usually been effected on a revolving grindstone; in ancient times a fixed stone was always used, on which the surface and edges of axes or hatchets were ground by friction.

"A Naturalist's Notes off Mull," by "Nether Lochaber," in *Good Words*, is a chatty account well worth reading.

Blackwood's Magazine contains a paper by Prof. Andrew Seth on "Man's Place in the Cosmos," being a criticism of Prof. Huxley's Romanes lecture on "Evolution and Ethics." Mr. J. Bickerdyke writes on "Successful Fish-culture in the Highlands." He explains some of the facts and principles which should be understood and considered before Highland fish-culture is attempted, and illustrates his subject with an account of some experiments made by Mr. Stewart at Kinlochmoidart.

An article on "Anthropometry as Applied to Social and Economic Questions" is contributed by Mr. C. Roberts to the *Humanitarian*. In it we note that the mean height of Fellows of the Royal Society is given as 5 feet 9·76 inches.

We have also received the *National Review* and the *Century*, but neither contains any articles of scientific interest.

EXPERIMENTS ON FLYING.

If we imagine the linear dimensions of a bird increased n times, its weight will be increased n^3 times. On the other hand, the work necessary to keep it flying will, as Helmholtz has shown, increase n^7 times.[1] Now, we can assume that the power, that is to say, the amount of

FIG. 1.

work that can be done in the unit of time, increases in proportion to the weight, or even less. Helmholtz, therefore, concluded that large dimensions are a disadvantage, and that there is a limit beyond which the power will become inadequate to the increased weight. This limit, in his opinion, is already attained in the largest birds, whose bodies appear to be constructed with the utmost economy in weight, and whose constitution and food seem adapted to furnish the highest power. And he therefore thought it improbable that man would ever be able to fly by his own power.

To these discouraging observations, however, some objections may be raised. First, the work necessary to keep a bird flying horizontally depends largely on its horizontal velocity. It decreases with increasing velocity up to a certain limit, when, on account of the friction, too much work must be spent on the horizontal component of the movement. The air will carry a body moving horizontally better than a stationary one, for the same reason that thin ice will sometimes carry a skater, but break under his dead weight. The moving skater is carried as if he rested on long skates that spread his pressure over a large area. The work which is expended in flying horizontally with a sufficiently high velocity may, in spite of Helmholtz's observations, be quite within the reach of human power. The difficulty, then, would only be to start and to arrive at this velocity, and this difficulty might be met by special contrivances. The size of a flyer might therefore be increased many times without losing the possibility of quick horizontal flight, though birds must be able to do without such contrivances for starting and arriving at the necessary velocity.

[1] Helmholtz, *Gesammelte Abhandlungen*, bd. 1, p. 165.

A second objection is that we see many birds—and especially the large birds—when soaring, evidently doing an extremely small amount of work, or none at all, but nevertheless moving rapidly, and even rising to great heights. It seems certain that the wind must do the work for them. The experiments of O. Lilienthal have shown how this is effected. He has made diagrams of the direction of the wind blowing over a plain, and has found it to be on the average three degrees upwards.[1] His idea is that the lower regions of the air are retarded by friction against the earth, and that it is therefore heaped up. Of course the rising air or an equal amount would have to come down again somewhere, and this might take place in calm weather. But however this may be, the wind in some way or other does the necessary work for soaring birds. With a bird of linear dimensions increased n times, this work, it is true, would only increase in proportion to the surface of the wings, that is, proportional to n^2, while the weight increases proportional to n^3. But for man there would be no difficulty in constructing the wing surface much larger in comparison than that of a bird.

The principal difficulty would lie in the management of the apparatus, in keeping the surface in the right position according to the variations of the wind, and according to the direction that one intends to follow. Perhaps it is not greater than the difficulty a skater meets with in keeping his balance while moving in the direction he pleases; but the consequences of a wrong movement are worse. O. Lilienthal seems to me to have taken a step in the right direction by trying to learn

FIG. 2.

soaring.[2] The accompanying illustrations, which are reproductions of instantaneous photographs taken in Steglitz, near Berlin, show the way he slides down a

[1] O. Lilienthal, "Der Vogelflug," p. 115; see also No. 55 of *Prometheus*, p. 37.
[2] See his article in Nos. 204 and 205 of *Prometheus*, from which the illustrations are taken.

slight decline of 10° or 15°. The shape of the wings is not flat but slightly curved. The experiments recorded in his book, "Der Vogelflug," show that the curved form has decided advantages both as regards the amount and the direction of the resistance. The wing surface is 15 square metres. It is not safe to take a larger surface before having learnt to manage a smaller one. He takes a sharp run of four or five steps against the wind, jumps into the air, and slides down over a distance of about 250 metres. By shifting his centre of gravity relatively

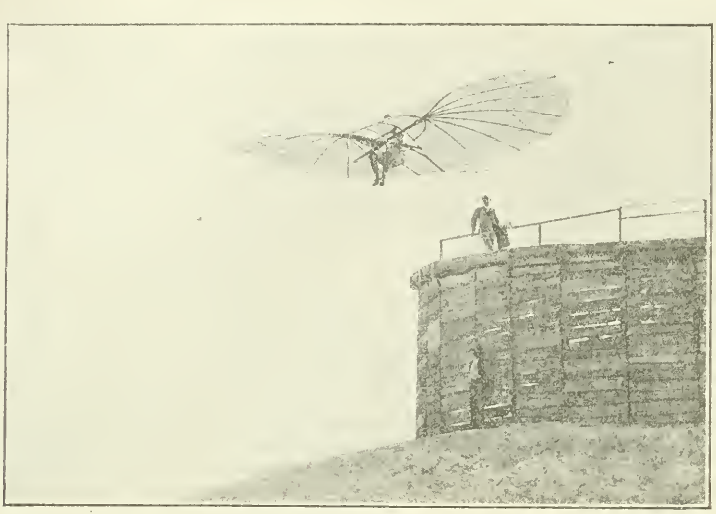

Fig. 3.

to the centre of resistance he can give the wing surface any inclination, and thereby can, to a certain extent, either slide down quicker, or slacken the movement, or alter the direction. If the wind is not too strong, and the surface of the apparatus not too large, I think there is very little danger in this kind of practice. If it is taken up by a great many people, improvements of the apparatus are sure to follow, and the art of keeping one's balance in the air will be developed. Perhaps this is the road to flying. At any rate it must be fine sport.

C. Runge.

NOTES.

The funeral of the late Prof. Tyndall took place on Saturday, in the parish churchyard at Haslemere. It was the desire of Mrs. Tyndall that the assemblage upon that sad occasion should not be large, so the mourners were chiefly Tyndall's close friends. Among them were the following men of science:—Prof. Huxley, Sir Joseph Hooker, Sir James Crichton Browne, Lord Rayleigh (representing the Royal Institution), Sir John Lubbock, Prof. Michael Foster (representing the Royal Society), Prof. Rücker (representing the Royal College of Science), Prof. Williamson, the Hon. Rollo Russell, Mr. Alex Siemens (representing Sir William Siemens), Dr. Buzzard, and Dr. Atkinson. These mourners are eminent in many different branches of science; and it is hardly too much to say that their presence not only marked the regard in which Tyndall is held in our best scientific institutions, but also testified to the grief of all students of natural knowledge at the loss of one of the pioneers of the scientific movement in England.

A special general meeting of the members of the Royal Institution will be held on Friday, December 15, to pass a vote of sympathy and condolence with Mrs. Tyndall on the occasion of the death of Dr. Tyndall, who was Honorary Professor of Philosophy of that Institution.

The death is announced at Paris of the biologist Dr. Chabry, known for his work in experimental teratology.

The Muséum d'Histoire Naturelle lost its able conchologist, M. Paul Fischer, on the 29th ult. He was born at Paris in 1835, and entered the palæontological laboratory of the Museum in 1861, remaining there until his death. The list of his contributions to the literature of science contains no less than three hundred titles, among which may be mentioned his "Histoire des Mollusques du Mexique," and the "Manuel di Conchyliologie," written in collaboration with M. Crosse.

The friends of Dr. Julius Hann, of Vienna, will be glad to learn that he has received from the Emperor the rare decoration for science and art (*Ehrenzeichen für Wissenschaft und Kunst*). This corresponds to the Order Pour le Mérite in Prussia, but is bestowed very charily, the total number of holders of it being only about a dozen. The actual decoration received by Dr. Hann had been set free by the death of Prof. J. Stefan, the physicist.

Prof. Riggenbach has been elected a Correspondent of the Paris Academy, in the place of the late Dr. Colladon.

Dr. J. Russell Reynolds, F.R.S., has been elected President of the Royal College of Physicians, in the place of the late Sir Andrew Clark.

The eleventh International Medical Congress will be held in Rome, from March 29 to April 5, 1894.

A Reuter's telegram from Berne announces that the Federal Council has decided to introduce the time of Central Europe into the Swiss postal telegraph, railway, and steamship services on June 1, 1894.

A prize of 3000 liras is offered by the R. Istituto Veneto di scienze lettere ed arti, for the most important innovation in Venetian pisciculture. The research for which the prize will be awarded may relate to the artificial hatching of the eggs of any important species of marine fish, the introduction of new species, improvements in methods of ostriculture, or the production of better kinds of fish.

For some time negotiations have been in progress for the purchase of the Little Barrier Island, with a view to setting it apart as a home for New Zealand fauna. We are glad to learn that the island has now been obtained from its owner, and that there is nothing to prevent the scheme being carried into effect.

The *Kew Bulletin* (Appendix i. 1894) contains a list of seeds of hardy herbaceous plants and of trees and shrubs available for exchange with colonial, Indian, and foreign Botanic Gardens, as well as with regular correspondents of Kew. No application for seeds can be entertained after the end of next March, except from remote colonial possessions.

The Director of the Botanic Garden of Rio de Janeiro has prepared and issued a list of plants cultivated there, and offered in exchange. A descriptive catalogue will shortly be published containing a description of each separate species in the Garden.

THE weather during the past week has been very unsettled over the whole of the British Isles, owing to the approach of several large depressions from the Atlantic. On the 6th a large disturbance passed eastwards to the north of Scotland, causing south-westerly gales in the north and west, and during the night of Thursday, the 7th, another deep depression advanced from the south-westward, attended by serious gales in all parts, but of great severity in Scotland and in Scandinavia. The barometer at Stornoway fell to the exceptionally low reading of 27·97 inches during the afternoon of the 8th, giving a difference in the pressure of nearly an inch and a half between the extreme north and south of our islands. Further disturbances arrived from the westward both on Sunday and Tuesday, again causing gales from the south-east and south. The storm on the latter day was chiefly restricted to the southern parts of England and the northern parts of France, and has not been exceeded in violence by any that has visited our southern counties this season. Several places reported force 11 of the Beaufort wind scale. Much rainfall and some sleet accompanied these various disturbances; in the north of Scotland 1·2 inch of rain was measured on the morning of the 9th, and the Meteorological Office Reports for the week ended the 9th inst. show that in that district the rainfall greatly exceeded the average, the total amount being 2·6 inches, while in most of the English districts the fall was less than the average.

IT is now known that the earthquake which affected Tashkend on November 5, was also felt in other parts of Russian Turkestan. At Samarkand it was felt one minute later than at Tashkend—that is, at 8h. 23½m. a.m., and pretty strong oscillations of the soil lasted for about 1½ minutes. Crockery was shattered, and the water in the ponds and irrigation canals was set in motion. At Marghelan the strongest shock took place at 9h. 35m., and lasted for about five seconds; it was followed by a feebler one about three minutes later.

ON November 5, the magnetic instruments at Potsdam were disturbed in a manner which showed that a distinct earthquake had reached the observatory. The supposition that such a cause produced the movements of the needles was afterwards confirmed by the record of the seismometer of the geological laboratory of the Faculty of Sciences at Grenoble. From the magnetic curves at Potsdam it appears that the wave reached the observatory at 5h. 4m. 50s. a.m. (Potsdam mean time), and produced the greatest effect at 5h. 8m. 55s., a vibration also being recorded at 5h. 7m. 15s.. According to *Comptes Rendus* of November 6, the shock was first felt at Grenoble at 4h. 56m. 35s. (Potsdam time), hence the time taken to travel a distance of about 956 kilometres was 8m. 15s. The rate at which the wave was propagated was therefore about 1·94 kilometre per second. It is estimated that the time can be read off from the magnetograph curves with an accuracy of ten seconds.

A FEW months ago the President of the Alpine Club invited the co-operation of the Government of India in obtaining a record of observations on the movements of glaciers in the Himalayan Range, to supplement a similar record maintained of the movements of glaciers in Europe. Believing that such a record would prove of importance to geological and meteorological science, the Government have communicated with officials and others who are stationed in or near the snows, or who may visit from time to time the glacial regions of the Himalayas. Copies of the Alpine Club's memorandum of instruction in glacier observation have been forwarded to the Foreign and Military Departments of the Government of India, the Governments of the Punjab, North-Western Provinces, and Oudh and Bengal, the Meteorological Reporter, and the Director of the Geological Survey, for distribution to such officers as may be in a position to supply the requisite information. The energetic action of the Indian Government in the matter deserves high praise, and it will doubtless result in some interesting data being obtained.

A COPY of the splendid volume published in honour of M. Pasteur's jubilee has been sent to us. It opens with a brief account of the formation of the memorial committee; this is followed by a reprint of the address delivered by M. C. Dupuy at the jubilee celebration, and of the numerous addresses and telegrams received from all parts of the world. The volume also includes five beautiful plates, three of which represent medals struck in M. Pasteur's honour, one the investigator himself in his laboratory, and one is a fac-simile of the address presented by the Stockholm School of Medicine. This testimony of the esteem in which Pasteur is held brings to our mind the words, "Wisdom raineth down skill and knowledge of understanding, and exalteth them to honour that hold her fast."

AT the Adelaide meeting of the Australasian Association for the Advancement of Science, a lecture was given by Mr. C. W. de Vis, on the "Diprotodon and its Times." Popular interest has lately been aroused in this subject owing to an important discovery of fossil marsupial bones at Lake Mulligan. Mr. de Vis pointed out the mistake of the current idea that the Diprotodon was a gigantic kangaroo, any great resemblance between the two being confined to the teeth. In general build, Diprotodon was more like a wombat, but the bones of the thigh were even longer in proportion to those of the lower leg than is the case in the wombat, hence it might be concluded that the Diprotodon was less capable of rapid motion than the wombat. The spongy texture of the bones of the skeleton indicates that it frequented lakes and marshes. There were two species of Diprotodon found in Central Australia—*D. australis*, Owen (circa 6 feet high and 10 feet long), and *D. minor*, Huxley (circa 5 feet high and 8 feet long). The arid central plains of the present had been occupied in Diprotodon times by vast extents of luxuriant forest and richly vegetated districts, well-watered by wide rivers. The marsupials were even then the dominant type of life in Australia; lizards were also numerous, and some were of unusually large proportions, *e.g.* Megalania, an extinct "guana," 18 to 20 feet in length. Extinct forms of alligators and turtles infested the waters, and amongst the fishes was the still existing Ceratodus. The remains of a varied bird fauna have been well preserved in the same deposits. This fauna included some ancestral forms connecting, on the one hand, the wingless birds of New Zealand with the Australian emus, and, on the other hand, the Australian birds with the New Zealand Apteryx. Mr. de Vis was inclined to attribute the disappearance of so many of these ancient forms of life from Australia quite as much to senile decay as to altered climatic influences.

THE slow ascensional movement of Scandinavia, evidenced by the displacement of tide marks, the peculiarities of Scandinavian lake fauna, and other geographical and geological phenomena, is subjected to mathematical investigation by M. A. Badonrean, who, in the *Comptes Rendus* of last week, treats the subject from the point of view of thermal expansion. At the time of the last glacial epoch, the Scandinavian ice-sheet covered the greater portion of the peninsula, as well as Finland and the Baltic, the area of this sheet being about 1500 km. in diameter. Where the soil touched and partly liquefied the mass of ice, its temperature must have been 0° C. At the present time, the mean temperature of the soil over the area of the ancient ice-sheet is 3° C. Taking the coefficient of expansion of the rocks as eight-millionths, the elevation of the centre of the ice-cap is calculated at 229 m., and the isoanabatics, or lines of equal

elevation, should be parallel to the contour. De Geer's map of these isoanabatics, traced in 1890, satisfies these conditions, allowance being made for the want of homogeneity in the rocky mass, and the want of fixity of its borders.

An interesting account of a fine series of glacial potholes on Cooper's Island, Little Harbour, Cohasset, U.S., is given by Mr. William O. Crosby, in a paper on the "Geology of the Boston Basin" (Occasional Papers of the Boston Society of Natural History, IV.). It is shown that the potholes were formed by *moulins*, or glacier mills, and Mr. Crosby discusses a question raised in these columns a short time ago, viz. why, as the ice-sheet moves continuously forward, carrying the crevasses and *moulins* with it, the potholes escape elongation in the direction of the movement? The true explanation of many glacial potholes is found in the fact, that a crevasse closes as it is carried forward by the general movement of the ice, a new one subsequently being formed just where in relation to the land at the margin of the glacier the former one existed. This explanation, however, is not applicable to the Cohasset potholes, and in place of it Mr. Crosby makes the suggestion that a *moulin* may remain approximately stationary, while the ice moves on, through the backward erosion and melting of its up-stream side; and that when a pothole is formed at the bottom of a *moulin*, it is not the direct impact of the water upon the face of the ledge that does the work, nor do the stones carried down by the water wear the ledges appreciably by their direct fall, but the pothole is due to their subsequent movement, and especially their rotation, by the water. This rotation implies an antecedent depression or hollow to hold the stones, and thus the conditions are seen to be essentially the same as for ordinary river potholes. Since the rotation of stones in a pre-existing hollow appears to be an essential condition of glacial as of other potholes, and the *moulin* simply supplies the power, it would seem to make little or no difference whether the water plunges into the up-stream side, the middle, or the down-stream side of the hollow. The pothole is made where the hollow exists, and during the progress of a *moulin* across the hollow, there would not, apparently, be any marked tendency to elongate it. In the case of a linear group of potholes on the ice-slope of a ledge, concludes Mr. Crosby, it is reasonable to suppose that the upper one, which on Cooper's Island is always the smallest and most indefinite, marks the shifting position of the *moulin*, and that the others were formed by the subglacial flow of water from the bottom of the *moulin*.

It has been supposed, says Mr. A. J. Jukes-Browne, in the *Geological Magazine* for December, that the total amounts of silica existing in the chalk with flints and the chalk without flints respectively, are very nearly equal; and this supposition favours the theory that flints have been formed by some process of segregation after the consolidation of the chalk containing them. It is generally conceded that the silica from which such flints were made was a soluble form like that of sponge spicules, diatoms, or radiolaria; hence by chemical analyses, aided by microscopical discrimination between crystalline and colloid siliceous particles, it is possible to determine whether flintless chalk always contains soluble silica, and whether chalk with flints contains little or none. Mr. Jukes-Browne has made this investigation, and he finds that there is no definite relation between the occurrence of flints and the absence or presence of soluble silica in the surrounding chalk. He thinks that chalk which is now destitute of any remains of siliceous spicules, has, since it became chalk, always been destitute of such spicules. These conclusions have a very important bearing upon the question of the formation of flints.

In a recent number of the *Comptes Rendus*, M. A. Delebecque gives the results of some observations made last summer on water from various depths in inland lakes, which show that the amount of solid matter in solution increases with the depth. Thus in the lakes quoted below the amount of dissolved solid matter in grammes per litre was:—Annecy, surface 0·138, bottom (65 metres) 0·157; Aiguebelette, surface 0·114, bottom (71 metres) 0·1605; Nantua, surface 0·154, bottom (43 metres) 0·190; Saint-Point, surface 0·152, bottom (40 metres) 0·182; Remoray, surface 0·1605, bottom (27 metres) 0·205; Crozet, surface 0·0275, bottom (37 metres) 0·0368. The water samples were collected about 3 metres above the bottom, by means of Dr. H. R. Mill's water-bottle. M. Delebecque agrees with Dr. Duparc, of Geneva, that the small amount of dissolved matter in the surface water is due to its removal by the calcareous organisms which swarm in the upper layers.

The *Philosophical Magazine* for December contains a paper, by Sidney J. Lochner, on the elongation produced in soft iron by magnetisation. The author undertook the investigation of this subject in order, if possible, to settle whether the experiments of Bidwell or Berget represented what really happens. In order to measure the elongation, what was essentially a Michelson's interferential refractometer was made use of, which was capable of measuring an elongation of a millionth of an inch. The bar of iron, whose elongation was to be measured, was placed inside a long magnetising coil, and carried at one end one of the mirrors of the refractometer. The expansion due to the heating effect of the coil being slow, while that due to magnetisation was rapid, the two could be distinguished. The author finds that, for a given magnetising field, different elongations are produced according to the manner in which the magnetising current is applied. Thus different elongations were produced in the cases where the current had been turned on suddenly, or had been applied gradually; and in the latter case it made a difference whether the current had reached its final value by increasing slowly, or by decreasing slowly from a higher value. Another peculiarity observed was that if the current be gradually increased from zero, at a certain point a maximum expansion is reached; after this a further increase of the current will produce a decrease in the elongation; if, however, instead of increasing the current when the maximum is reached, it is gradually decreased, it is possible to obtain a still greater elongation. The observations show that the expansion is a function of the ratio between the diameter and length of the bar, and that the elongation varies approximately directly as the square root of this ratio; also, the expansion varies directly as the permeability. The amount of current required to produce the maximum expansion also depends on the ratio between the diameter and length.

The bacterial efficiency of porous cylinders in the filtration of water for domestic purposes is the subject of considerable discussion just now. Kirchner (*Zeitschrift f. Hygiene*, vol. xiv. p. 307) found in his experiments with water purposely infected with typhoid bacilli, that such filters were incapable of arresting these organisms. Large quantities of typhoid infected broth were added to the water before filtration, and the filtrate after 48 hours was found to contain very large numbers of typhoid bacilli. Dr. Schöfer, in a recent number of the *Centralblatt f. Bakteriologie*, vol. xiv. p. 685, gives the results of his investigations of porous cylinders as regards their retention of typhoid bacilli. In these experiments as small a quantity as possible of nutritive material was added with the typhoid organisms to the water (previously sterilised), and even after 24 days the filtrate was found to be perfectly sterile, although the unfiltered water was freshly infected with typhoid bacilli no less than twelve times during the investigation. Very different results were,

however, obtained when broth was purposely added to the unfiltered water, an addition of as little as 5 c.c. to 600 c.c. of water so stimulating the growth of the typhoid organisms, that two days later they appeared in the filtrate; the numbers present, however, gradually decreased, but on again adding 5 c.c. of broth they rose on the following day from 9 to 6,139 per c.c. This large increase was due to the rapid multiplication of the few isolated bacilli still remaining in the pores of the filter in consequence of the supply of food material to the water in the shape of broth, for no fresh infection with typhoid organisms had taken place. Dr. Schöfer is of opinion that typhoid bacilli as present in water, under ordinary circumstances, are not supplied with the requisite conditions for their growth and multiplication, and are, therefore, incapable of growing through these porous filters, and so reaching the filtrate; but these conditions are, however, undoubtedly furnished when a sufficient supply of food material is contained in or added to the water, under which circumstances the cylinders are unable to retain them. These experiments not only explain the unsatisfactory results obtained by Kirchner, but indicate what precautions should be taken in the bacteriological investigation of such filters.

THE last two parts of the well-known "Notes from the Leyden Museum," forming parts 3 and 4 of vol. xv., were published in July and October. They contain numerous papers describing new or rare species of mammals, birds, reptiles, &c., added to the museum. Among the articles we notice one which is by F. E. Blaaum, the Secretary of the Zoological Society of Amsterdam, on a comparative list of the birds of Holland and England. Holland, although so much smaller than the United Kingdom, is the regular abode, at different seasons, of 221 species of birds, whilst the British Islands can only boast of 211. Dr. R. Horst continues his descriptions of earth-worms, giving a list of species found, for the most part by Dr. H. ten Kate, during his journey in the Malay Archipelago in 1891. A large number of the species belong to the genus Perichæta, of which no less than seven species are described as new, bringing the number of the species of this genus already found in the Malay Archipelago to thirty-three. The following note, by Dr. Jentink, will be interesting to others besides book collectors. In the Proceedings of the Zoological Society of London for 1880 (p. 489), Mr. F. H. Waterhouse gives the dates of the publication of the parts of Sir Andrew Smith's "Illustrations of the Zoology of South Africa," and states that as the copy he examined "did not contain plates 18 and 38 (Mammalia), he had examined three or four other copies, and as neither of these plates are to be found in any of these, he presumed they do not exist." Now, in the copy in the Leyden Museum's library, plate 38 is present, but plates 18 and 37 are wanting, and at the bottom of the page containing an index of the Mammalia, there is the following: "Plates 18 and 37 *not* published." Librarians will call to mind how often the collating of this fine work has perplexed them.

THE Royal Meteorological Institute of the Netherlands has recently issued its *Jaarboek* and *Onweders in Nederland* for the year 1892. The first work has been regularly published for forty-four years, and now contains hourly observations taken at four stations, in addition to those taken at specified hours at a number of other places. It also contains observations taken in Surinam (South America) and French and Upper Congo. The second work is the thirteenth of the series, and contains a discussion of each of the thunderstorms which have occurred during the year, with reference to the general weather conditions over Europe.

WE have received from Mr. John Elliot, the Meteorological Reporter to the Government of India, the daily weather charts of January, 1893, for the Indian sea and land areas.

MM. J. B. BAILLIÈRE ET FILS, Paris, have issued an ornithological bibliography containing announcements of five or six hundred works on ancient and modern birds.

HERR MORITZ, Berlin, has published Nos. 1–4 of his "Antiquariats-Katalog." The catalogues are of special interest to geographers and anthropologists, and they contain many rare works.

MESSRS. FRIEDLÄNDER AND SON, Berlin, have sent us Nos. 16–21 of their "Naturæ Novitates." These bibliographical lists contain works in every branch of science, and are invaluable to the scientific book-hunter.

ANOTHER catalogue, recently issued, is one containing the titles of works on geology offered for sale by Messrs. Dulau and Co.

THE first number of the *Psychological Review* will be published early in January, by Messrs. Macmillan and Co., London and New York. It will be edited by Profs. J. Mark Baldwin (Princeton) and J. McKeen Cattell (Columbia). The *Review* is intended to contribute to the advancement of psychology by publishing the results of original research, constructive and critical articles, &c., in connection with the subject.

THE *American Naturalist* for November contains several interesting articles. Mr. Howard Ayers writes on the genera of the Dipnoi Dipneumones, and Dr. J. Weir gives a number of examples of animal intelligence. A collection of molluscs from North-Western Louisiana is described by Mr. T. Wayland Vaughan, and Mr. H. C. Mercer compares the Trenton and Somme gravel specimens with ancient quarry refuse in America and Europe.

MESSRS. NEWTON and Co. have issued a new catalogue of optical lanterns, microscopes, and polariscopes for demonstrations in science. There are very few class experiments that do not admit of being projected upon a screen by means of the many good lanterns in the market, and certainly there is no better method of demonstrating scientific facts to a large audience. One of the finest lanterns made by Messrs. Newton is the triple rotating electric lantern designed by Sir David Salomons. We learn that the Royal Society has just ordered an instrument of this kind.

A GENERAL method of artificially preparing crystallised anhydrous silicates similar to the naturally occurring pyroxenes, is described by Dr. Hermann Traube in the current *Berichte*. It consists in precipitating the particular metallic silicate, which it is desired to obtain in anhydrous crystals, by the addition of a solution of sodium silicate to a solution of a salt of the metal. The amorphous hydrated silicate thus precipitated is heated to a high temperature with boric acid for some hours. When most of the boric acid has volatilised, the anhydrous metallic silicate is usually left in the form of good crystals. Ebelmen has already succeeded in artificially preparing the magnesium pyroxene $MgSiO_3$ by this method; and Dr. Traube now extends its application. When precipitated silicate of zinc, for instance, obtained by the addition of a solution of sodium silicate to one of zinc sulphate, is dried, and then heated with eight times its weight of fused boric acid, in a platinum crucible, for a few days, to the highest temperature of a porcelain manufacturer's furnace, a large proportion of the boric acid disappears by volatilisation, and upon extraction of the remaining portion from the cooled residue with water, beautiful little insoluble crystals of anhydrous silicate of zinc, $ZnSiO_3$, remain. When examined under the microscope these crystals are observed to be perfectly transparent prisms with domal terminations. Their optical characters indicate that they belong to the rhombic system of symmetry. This artificial silicate of zinc would thus

appear to be isomorphous with the naturally occurring magnesium silicate, enstatite, $MgSiO_3$. The method is also applicable to the synthesis of complex mixed silicates, and it is possible by means of it to reproduce almost any of the naturally occurring silicates of this class.

At the last meeting of the Southern District Association of Gas Engineers and Managers, Dr. L. T. Thorne gave an account of further experiments with the new process for enriching coal gas by means of oxy-oil gas. Dr. Thorne has been enabled to carry out an exhaustive series of tests at Huddersfield, where the process is now in actual operation. His conclusions are summarised as follows: (1) The addition of oxygen to oil gas, preferably while the latter is still hot, not only increases the illuminating value of the oil gas when employed directly as illuminant, but also when it is used for purposes of enrichment. (2) Oxy-oil gas is a highly permanent gas, and when used as an enricher of coal gas actually increases the stability of that gas. (3) Enrichment of coal gas by oxy-oil gas would cost about one-third of a penny per candle per thousand cubic feet. Dr. Thorne concludes by expressing the opinion that the experimental results place oxy-oil gas at the head of the enriching processes yet known, and fully justify the favourable view of the process which was expressed in an earlier communication. With regard to the actual working of the Huddersfield plant, we learn from *London*, the organ of the London County Council, of November 30, that the Huddersfield Corporation have now used the new gas continuously for over two months, and have obtained a steady white flame, affording a better light, while enabling a saving to be effected at the rate of £10,700 per annum. They are now using 36,000 cubic feet of the new gas per day for enriching the ordinary product. They have been in the habit of enriching their ordinary gas, which is of about sixteen candle power, to the extent of four additional candles, by means of cannel coal. The cost per candle at Huddersfield, using Yorkshire cannel, has been about three-halfpence per cubic foot. With the new plant of the oxy-oil process the actual working cost is at present less than a halfpenny per candle per thousand cubic feet, and will eventually be still less by thirty per cent. or more, as crude petroleum is rapidly becoming cheaper. Moreover, the coke produced from cannel coal is so useless that the Huddersfield Corporation have been unable to dispose of it, even to give it away. Under the new process they find no difficulty in selling all the coke they can produce, for seven shillings and sixpence per ton. The saving due to enrichment amounts to £7,700 per annum, and the gain from sale of coke to £3,000, results which will have the practical effect of reducing the price of gas to the consumers at Huddersfield by at least threepence per thousand cubic feet, while supplying them with a more cheerful light which is stable even in winter.

Notes from the Marine Biological Station, Plymouth.—There has been little that is novel to record lately, owing to the inability of our small boats to face the stormy seas. Last week several specimens of the Teleostean *Sciæna umbra* were brought in, and the Nemertine *Eupolia curta* (second capture) and the Crustacean *Gebia stellata* were taken in the Sound. The floating fauna is poor as a rule, but there is an increasing number of Annelid trochospheres, *Scyphonautes* and Opisthobranch veligers. There is a noteworthy scarcity of Medusæ. The Anthozoa *Alcyonium digitatum* and *Cereus pedunculatus* (= *Sagartia bellis*), and the Crustacea *Pandalus annulicornis*, *Crangon vulgaris*, and one-year-old *Carcinus mænas* have begun to breed.

The additions to the Zoological Society's Gardens during the past week include a Pale-headed Parrakeet (*Platycercus pallidiceps*) from North-East Australia, presented by Mr. C. B. Lewis; two Common Crossbills (*Loxia curvirostra*), a Song Thrush (*Turdus musicus*) British, presented by Mr. H. C. Martin; two Alligators (*Alligator mississippiensis*) from the Mississippi, presented by Mr. Austin E. Harris; a Chacma Baboon (*Cynocephalus porcarius*, ♀) from South Africa, presented by Mrs. Rowland Tomson; two Leopards (*Felis pardus*) from India, deposited; thirteen Rufous Tinamous (*Rhynchotus rufescens*) from Brazil, purchased; a Japanese Deer (*Cervus sika*, ♀) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

New Notation for Lines in Spectrum of Hydrogen.—The application of the photographic plate to that important instrument of physical astronomy, the spectroscope, has brought to our view, in addition to the four well-known lines of hydrogen in the visible part of the spectrum, another set of similar lines, the first of which, having a wave-length less than that of H_1, coincides with one component of H_1 of the broad double line in the solar spectrum which Fraunhofer termed H. The second component, written H_2 or K, is wanting in many stars of Vogel's class Iα; yet its coincidences with the line H_2 or K, where in this class another line in the region of H_1 makes its appearance, became established, so that no opportunity offered itself to make a special nomenclature for the two first lines above *Hd* outside of the star's spectrum situated in the violet region. The other lines Huggins named with the Greek characters α, β, γ, &c. A new system of nomenclature, suggested by Prof. Vogel, in the *Astronomischen Nachrichten* (No. 3198), has many points in its favour. The four lines in the visible region, C, F, G, and *h*, retain their old signs of Hα, Hβ, Hγ, Hδ, but H or H_1 is here changed to Hε, and the α, β, γ lines of Huggins to Hζ, Hη, &c., thus making the nomenclature thoroughly consecutive. Prof. Vogel says that in future he shall adopt this new notation, and that Dr. Huggins has also agreed to the arrangement, viz. that the hydrogen lines should always have the element sign H coupled with a Greek letter as index, as shown in the following table, in which are given the new and old notations with the wave-lengths:—

Wave-lengths.	Notation. New.	Notation. Old.
656·3μμ	Hα	Hα or C
486·1	Hβ	Hβ or F
434·1	Hγ	Hγ (written often wrongly with G)
410·2	Hδ	Hδ or *h*
396·9	Hε	H or H_1
388·9	Hζ	α
383·6	Hη	β
379·8	Hθ	γ
377·1	Hι	δ
375·0	Hκ	ε
373·4	Hλ	ζ
372·2	Hμ	η
371·2	Hν	θ
370·4	Hξ	ι

The Spectrum of Nova Normæ.—Prof. Pickering, in *Astronomischen Nachrichten*, No. 3198, gives some details about the discovery of the new star in Norma. The star was found by Mrs. Fleming on October 26 when, examining a photograph of the *spectra* of the stars in this constellation, the negative having been taken by Prof. S. J. Bailey at the Arequipa station on July 10, 1893. Comparing the spectrum with that obtained in the case of Nova Aurigæ, nearly the same dispersion having been employed, it seems that they are nearly identical—"about a dozen lines are visible in each, and are identical in wave-length." The line F, although bright in both stars, is more intense in Nova Normæ, and, further, is more intense than any other line, while G was generally strongest in Nova Aurigæ. With regard to the time of the outburst of this new star, photographs indicate that it must have occurred within the first ten days of July 1. A photograph taken June 21,

1893, shows no trace of it upon the plate exposed to that region, while charts of the same region taken on June 6, June 10, July 21, 1889; May 16, May 16, June 10, June 23, June 23, 1891; May 7, and May 27, 1893, also give no indication of a star in that position. The similarity of the spectra of these two new stars is of interest, as Prof. Pickering points out, in that it has proved a means of discovering one of these objects, and that, if confirmed by other new stars, it will indicate that they belong to a "distinct class resembling each other in composition and physical condition." The nearest catalogue stars to which the Nova lies are Cord. G.C. 20,940 and Cord. G.C. 20,926 of the 8 and 8·75 magnitude respectively, the Nova being nearly midway between them. We may add that the above communication seems to throw some doubt on the accuracy of the note we wrote three weeks ago (November 23), with reference to Prof. Kapteyn's search through his Durchmusterung. Until the exact position of Nova Normæ is obtained, one cannot of course make any statement, but it seems probable that Prof. Kapteyn's and Mrs. Fleming's stars are not the same.

PROF. RUDOLF WOLF, OF ZURICH.—We are very sorry to have to record this week the death of Prof. Rudolf Wolf, the well-known director of the Zurich Observatory. He died at midday on November 6, after a short illness, at the age of seventy-eight years. By his death astronomical science has lost one of her most devoted servants. It was through his work, coupled with that of Schwabe, that the existence of the periodicity of the sunspots was without doubt first accepted, and its length determined to be eleven and one-ninth years. The deceased was, among other things, the author of the work on the "Geschichte der Astronomie," and also of a "Tachen-buch für Mathematik, Physik, Geodäsie und Astronomie," both of which ran through several editions.

THE COMPANION TO THE *Observatory*.—The Companion for the year 1894 follows the same lines as it has done in former years. No additional matter has here been added, unless we mention the ephemeris for the elongations of the satellites of Mars, which planet comes into opposition during next year. We notice that in Mr. Denning's list of meteor showers, instead of November 27, he has this year thought fit to alter it to November 23–27, an alteration justifiable by facts. With regard to eclipses, on March 20–21 a partial eclipse of the moon will take place, but will be invisible at Greenwich. An annular eclipse of the sun, just visible as a partial one in Norway, Sweden, Eastern Europe, and Asia, occurs on April 5, while on September 14 a partial eclipse of the moon will be partly visible at Greenwich. The total eclipse of the sun, on September 28, lasts only for eleven seconds (maximum duration), and as the path of the centre of the shadow lies entirely across the Southern Indian Ocean, the occurrence is of little scientific interest. On November 10 a transit of Mercury across the sun's disc will be partly visible at Greenwich, the first contact taking place before sunset. The times are—

	Ingress. h.	m.	s.	Egress. h.	m.	s.
External contact ...	3	55	40	9	13	9
Internal ,, ...	3	57	23	9	11	26

For the sun in the zenith at the time of egress, the place of observation lies 63° W. and 17° S. or in Bolivia, South America, that for egress lying 142° W. and 17° S.

SOLAR OBSERVATIONS AT ROME.—In the September number of the *Memorie della Societa degli Spettroscopisti Italiani*, Prof. Tacchini contributes the results of the solar observations made at the Royal Observatory during the second and third trimestre of 1893. The same number also contains two large diagrams of the limb of the sun, the first showing the observations made at Catania, Palermo, and Rome, during the second three months of the year 1892, and the second indicating observations made at the last-mentioned place during June and July.

GEOGRAPHICAL NOTES.

MR. R. D. OLDHAM, Superintendent of the Geological Survey of India, read a paper at the last meeting of the Royal Geographical Society, on the evolution of the geography of India. He pointed out that the three main divisions of India were natural regions the individuality of which had been marked throughout a long range of geological time. The peninsula consists of very ancient land which has not been submerged since the early Palæozoic period, while the continental division has been frequently under water until Tertiary times, and the great plain is relatively recent alluvium. There is evidence from the close resemblance of fossil forms of a continuous land connection between India and Africa in the Cretaceous period. This former continent has been named Gondwana Land, and must not be confused with the hypothetical continent of Lemuria. It had disappeared by the end of the secondary period. At the close of the Cretaceous period there was an unparalleled outburst of volcanic activity contemporary with a series of great earth-movements which went far to give its present outline to peninsular India, and led to the first appearance of the extra-peninsular mountains. This activity continued during the Tertiary period. The depression at the base of the Himalaya, now filled up by alluvium, was simultaneously formed. The Indus was the original outlet of drainage from the Himalayan district, the river system splitting up later, and the diversion of the Jumna to the Ganges may even have occurred in historical times. The latter part of the paper gave an able summary of Indian types of scenery.

THE crossing of the eastern horn of Africa is fast becoming one of the commonplaces of travel, having been again accomplished this year by Prince E. Ruspoli, who, starting from Berbera in December last year, reached the Jub in March. The last number of the *Bulletin* of the Italian Geographical Society contains a letter giving an account of the journey and a sketch-map showing his route. Another Italian expedition, under Captains Bottego and Grixoni, made the journey by a somewhat different route about the same time.

THE *Verhandlungen* of the Berlin Geographical Society states that the Swedish traveller in Persia, Mr. Sven Hedin, has undertaken a serious attempt to reach Lhasa in the disguise of a Persian merchant. He will start from Leh, and follow the route of the Pundit Nain Singh to Tengri-Nor.

THE death is reported of Dr. D. Scott Moncrieff, of Harvard University, who had been making a journey of exploration, mainly with a view to ethnological observations, in Eastern Siberia. He left a Gilyak village near the mouth of the Amur for a sail in an open boat, on August 11, and nothing further was heard of him until a fortnight later his body was found on the coast of Sakhalin.

M. E. PONCINS, a French traveller, writes from Gilgit to the Paris Geographical Society under date August 26, that he has crossed the Pamirs, from north to south, and paid special attention to the source-region of the Oxus. He proposed to proceed to Simla, and there complete a full account of his journey.

THE source region of the Irawadi is still one of the most unknown parts of Asia, and it is satisfactory to learn that Captain Bower, whose recent journey in Tibet is well known, intends making explorations in that region during the present cold season.

THE meeting of the Paris Geographical Society on November 17 was devoted to the memory of the navigator Entrecasteaux, whose somewhat unfortunate voyage of discovery round the coast of Australia and amongst the islands of the Western Pacific was interrupted by his death in 1793.

UNVEILING OF THE JOULE MEMORIAL STATUE.

MANCHESTER claims the distinction of having been the home of two or our greatest men of science—Dalton and Joule—and it has shown itself worthy of the honour. A beautiful statue of Dalton has adorned the vestibule of the Town Hall for some years, and on Friday last, one of Joule, by Mr. A. Gilbert, was unveiled in the same place, the two philosophers standing face to face.

It was in 1889 that the Manchester Literary and Philosophical Society proposed to raise a memorial to Joule, and, to the credit of Manchester be it said, the suggestion was taken up with enthusiasm. On November 25 of that year, a meeting was convened by the Mayor of Manchester at that time (Mr. Alderman Mark), and was attended by a large and influential company. The

following resolution was then adopted:—"That this meeting desires to mark its deep sense of the benefits conferred on mankind for all time, as well as of the great honour which has accrued to this district, by the scientific work of the late James Prescott Joule, by the erection of a durable memorial of him in Manchester, in the form of a white marble statue." A representative committee was appointed to raise subscriptions to carry the resolution into effect, and the sum of £2611 was eventually obtained.

Almost the first act of the committee was to pass a resolution to the effect that the movement should be directed to secure not only a marble statue of Dr. Joule as a companion to that of Dr Dalton, but also a replica in bronze to occupy some public place in the city. This object was kept in view for some time, but eventually it was thought advisable to relinquish the idea. After abandoning the scheme of raising a bronze replica of the statue, it was decided that the surplus should be handed over to the Literary and Philosophical Society as a nucleus for the institution of a permanent Joule Memorial Fund, the income of which is to be employed, as the council of the Society may direct, for the encouragement and promotion of science.

The unveiling of the Joule statue was performed by Lord Kelvin, in the presence of a large company. The *Manchester Guardian* gives a full report of the proceedings, and from it we extract the following remarks made by Lord Kelvin in the course of his address.

The Literary and Philosophical Society had the distinguished honour of being really the cradle of Joule's work—first as Dalton's home, and afterwards as Joule's life-long scientific harbour. From very early days he kept constantly in touch with that Society. Many of his most important papers were first given to the world there, and during the last years of his life he was an exceedingly regular—it might almost be said a constant—attendant at the meetings of the Society. The citizens of Manchester did not require to be told what great things this Society in its rather more than a century's existence had done. Their presence in such numbers on that occasion showed how much they appreciated the results of that very effective scientific institution. Now he ought to say something of the electrical, mechanical, and chemical character of Joule's work, although to examine it properly would require the space not of one address, but of a whole course of lectures illustrated by experiments. A great surprise that came out very early in Joule's work was burning without heat—an absolutely novel idea which Joule developed most wonderfully and most magnificently by his experiments in the generation of heat in the voltaic battery, which in those days was the only source of electricity on a large scale. Joule was the first to develop the idea, and it came to him not as a bright flash of genius, but as the demonstrated result of years of hard, measuring, calculating work. This was the fundamental idea that pervaded all Joule's work. A few years later he expanded it in a wonderful way. About 1846, in a joint paper by himself and Scoresby, he brought out the wonderful, the truly philosophical, and at the same time startling idea that when a man or any other animal walked uphill, only a part of the heat or combustion of his food was developed, and that it was when the body was quiescent that the chemical attraction between the food and the oxygen dissolved in the blood developed its whole energy in actual animal heat. He showed, further, that the animal body was more economical for fuel than was any steam engine hitherto realised. This was a very far-reaching idea, and seemed to hold out prospects of greatly advancing the efficiency of the steam engine. That promise had not been lost. It was due to Joule, more than to any other individual, that the great improvement of surface condensation was now universal, although very rarely practised, indeed, before 1860 or 1862. Joule, about the year 1860, in working upon a little steam engine, applied a surface condenser on an entirely new principle, and in doing so he was led to think out a mode of getting heat out of the steam to be condensed without sending a jet of water into it, as on the old plan. But he (Lord Kelvin) had not yet touched upon Joule's great fundamental discovery, the discovery which was first in everyone's mouth—that of the mechanical equivalent of heat. They would understand that it was not merely by a chance piece of measurement that he stumbled on this result, which was afterwards found to be of great value. It was measurement, rigorous experiment and observation, and philosophic thought all round the field of physical science that made this discovery possible. Very early indeed in his working time Joule brought out the mechanical equivalent of heat, and in a paper read at the British Association at Cork in 1843, and afterwards in the *Philosophical Magazine*, he gave the number "772." Six years later a second determination gave him the same result, and twenty-five years later he made a third determination, which gave him the final and corrected result "772·56." In the year 1824 a great theory was originated by a very young man, who died only a few years later—Said Carnot, son of the Republican Minister, and uncle of the present President of the French Republic. It was he who made "Carnot's theory" a household word throughout the world of science; and great as was the French President, much as he had done for his country and the world, in after times his uncle would be always remembered as one of the most distinguished characteristics attached to that great name. Carnot's theory gave an important fundamental principle regarding the development of motive power from heat. Joule's work, on the other hand, so far as the mechanical equivalent was concerned, was the generation of heat by mechanical work. It was quite the middle of the century before Carnot's work began to attract attention; but Joule was early made acquainted with it, and after fighting a little against it as differing from his own theory, he of all others took it up in the most hearty manner. Lord Kelvin went on to say that he could never forget the British Association at Oxford in the year 1847, when in one of the sections he heard a paper read by a very unassuming young man who betrayed no consciousness in his manner that he had a great idea to unfold. He (Lord Kelvin) was greatly struck with the paper. He at first thought it could not be true because it was different from Carnot's theory, and after the meeting he and the reader of the paper, James Joule, had a long and thoroughly discursive talk on the subject, and he obtained ideas he had never had before, although he thought he too suggested something worthy of Joule's consideration when he told him of Carnot's theory. He had the great pleasure and satisfaction for many years, beginning just forty years ago, of making experiments along with Joule, which led to some important results in respect to the theory of thermodynamics. This was one of the most valuable recollections of his life, and was indeed as valuable a recollection as he could conceive in the possession of any man interested in science. Joule's initial work was the very foundation of our knowledge of the steam engine and steam power. Taken along with Carnot's work it had given the scientific foundation on which all the great improvements since the year 1850 have been worked out, not in a haphazard way, but on a careful philosophical basis. James Watt had anticipated to some degree in his compound engine and his expansive system the benefits now realised, but he was before his time in that respect, and had the complete foundation which Joule's mechanical equivalent and Carnot's theory had since given for the improvement of the steam engine. Might he be allowed, Lord Kelvin added, to congratulate the city of Manchester on its proceedings that day? When the cover was lifted from the statue of Joule, he felt deeply touched at the sight of the face of his old friend. To his mind it was a most admirable likeness, and the ideality of the accessory of the little model held in the hand seemed to him most interesting and most striking—he thought he might say poetical. That little model was not one of Joule's first or second, but of his third and greatest apparatus for the determination of the mechanical equivalent of heat—that by which he corrected the British Association's standard ohm, which he proved to be 1·7 per cent. wrong. Regarding that standard a diplomatic correspondence was now going on between our Foreign Office and other European Governments with a view to arranging the precise terms of the definition of the ohm, which was really first worked out by Joule. Lord Kelvin further asked to be allowed to congratulate the sculptor on the great beauty and the great success of his work, and added that Manchester now possessed statues both of the man who laid the foundation of the atomic theory in chemistry, and of the man who was the originator of the whole subject of thermodynamics. If the prosperity of Manchester did not depend on chemistry and on the steam engine and thermodynamics, he did not know upon what it did depend. The energy and industry of its inhabitants were no doubt essential to its success, but they must ever remember that the material prosperity of the city was as much dependent on philosophic thought as it was upon any material appliance whatever.

Sir H. E. Roscoe, M.P., in moving a vote of thanks to Lord

Kelvin for his address, mentioned that for thirty years he himself sat at the feet of Joule, whom he might therefore claim in some sense as his scientific father. He remained in constant communication with Joule up to the day of the philosopher's death. It was a great thing that in a city like Manchester, devoted as it was to industry and commerce, the citizens should be entitled to place in their Town Hall the statues of two such fellow-citizens as Dalton and Joule. Few cities in the world could boast of two greater men. In London, also, they had been doing something to show the appreciation in which not only this country but the world held Joule. A sum of money had been raised and placed in the hands of the Royal Society for the purpose of founding a Joule studentship, and on Thursday the Council of the Society resolved that the money should be spent in founding such a scholarship, to be awarded alternately in England and in other countries, for the purpose of encouraging young scientific men to walk in the steps of Manchester's great citizen. The first of those scholarships, of the value of £100, would be shortly awarded, and he thought he was not going too far when he said it would come to the city in which Joule lived and worked. He might mention that since the foundation of Owens College that institution could claim nine medallists of the Royal Society, and had they lived Prof. Jevons and Prof. Schorlemmer would have been added to the number. It would be seen, therefore, that Manchester had taken up the thread spun by Dalton and Joule, and that there was no reason to fear that their work would not be continued.

Prof. Osborne Reynolds seconded the resolution, which was adopted.

On the motion of Mr. Alderman Mark, seconded by Principal Ward, a vote of thanks was given to the Lord Mayor for presiding. At the conclusion of the proceedings the Lord Mayor and Lady Mayoress held a reception in the state apartments.

THE ETHNOLOGICAL MUSEUM AT LEYDEN.

IT is from twenty-five to thirty years ago that the interest in ethnology as a science was awakened. Ethnological objects are no longer considered by scientific men as mere curiosities; collections of them have ceased to be shops of foreign bric-a-brac. In America and in Europe, museums have arisen, variable in size and importance it is true, but all with the same object in view, viz. the study of man from his handiwork as illustrative of his mental development in various directions, in time as well as in space.

The realisation of the importance of collecting and studying ethnological material in distant lands has not come too soon. What has been done in this respect within the last twenty-five years surpasses all that has been performed in the centuries before, from the beginning of the circumnavigation of the globe to the early seventies of our century. The result of this has not only been the publication of valuable ethnological monographs and studies, but also the foundation of new, and the further development of existing, museums in Europe and America. Amongst the ethnological collections which have grown considerably are those of the National Ethnological Museum at Leyden. A pamphlet by the director, Dr. L. Serrurier, recently published under the very suggestive title of "Museum or Storehouse?" induces me to write the present notice.

The origin of this museum dates back as far as 1837, the year in which the Dutch Government purchased von Siebold's Japanese collections. This formed the nucleus of the little museum, which gradually increased by means of collections made in the Indian Archipelago by Macklot, Salomon Müller, von Rosenberg, and other naturalists. In the meanwhile von Siebold had returned to Japan, and the late Dr. Leemans was appointed acting director of the collection in 1859, as a part of the National Museum of Antiquities. A long period of inactivity then ensued until 1880, when it was decided that the ethnological department should become a separate museum, under the direction of Dr. Serrurier, until then curator of the Japanese department.

From that moment the museum sprang into new life. The period of curiosity shop had ceased for ever; and the institution was developed in the right direction. Many objects were properly identified, check lists and manuscript catalogues corrected and newly made,[1] relations with sister institutions established, exchanges made, and valuable objects and collections bought. Many residents in the Dutch colonies who hitherto had hardly heard of the existence of an ethnological museum at Leyden, now gladly presented or loaned their private collections to it. Nothing shows more clearly the extraordinary growth of these collections than the maps accompanying the pamphlet of Dr. Serrurier. On these maps—two of the world, and two of the Indian Archipelago—is indicated the number of groups of objects in the Leyden Museums representing special ethnological regions or areas. These groups refer to a very rational division or classification established by Dr. Serrurier and used in the Leyden Museum. One set of maps shows the condition of the collections in 1881, the other in 1893. A single glance at the maps is sufficient to illustrate the vast difference wrought in those twelve years. Southern Asia, the Orient, Africa, and North America were hardly or not at all represented in 1881, and so were many parts of the Indian Archipelago and South America, but in 1893 the ethnology of these countries can be studied in the museum by means of valuable and more or less representative collections. In short the collection has decupled in these twelve years, not to speak of the rich and varied anthropological section, entirely the work of the present director.

It would be only natural to suppose that collections of this importance were exhibited in a special building where they were not only safely stored but also made of interest to the public, as well as for professional men. Nothing is, however, farther from the reality than this supposition. To the amazement of foreign ethnologists, and every friend of science in fact, the Leyden collections are scattered, as Dr. Serrurier summarises, over not less than five different places—ugly, dark, and damp private houses, or other localities, all equally unfit for the conservation of the ethnological material. Thousands of precious objects are stowed away as in a storehouse, where moths and moisture are hard to fight against, and where the danger of fire is so much greater than elsewhere. Should ever a fire destroy these collections, the loss would, for the greater part of them, be irreparable; they could not be again collected. In many distant countries, all over the world, the inhabitants have given up their native industries, and are losing rapidly their originality in every respect, the result of their contact with Western civilisation.

An appendix to Dr. Serrurier's pamphlet, being a number of testimonies from different travellers and authors as to the disappearance of primitive conditions among foreign races, tends to prove the value of present ethnological collections and the necessity of collecting objects and data without delay, before it will be too late.

Irrespective, however, of the present buildings the museum collections are not quite what they ought to be, which perhaps is partly due to the fact that they are situated in a small old-fashioned city with a public—University students included—taking very little or no interest in ethnological exhibitions. If the museum were situated in a great city, say Amsterdam or The Hague, things might probably take a turn for the better, but still, as long as there is no special building, a thorough improvement will be impossible.

There are many things which the Ethnological Museum of Leyden ought to be, and should be, if proper attention was paid to it by the Dutch government. For a nation like the Dutch, which ranks third as a colonial power, a museum like this could be a sort of a bureau of ethnology, more or less similar to that of Washington, and a place where both University students and the general public could be taught sounder ideas about races of mankind which they have been used to consider as "savages."

For years past the director has called the attention of the Dutch government to this state of things. In each of his annual reports Dr. Serrurier has pleaded for the sake of a new and proper building with the ardour and conviction of a man who pleads for the thing to which he devotes his life and talents, but all in vain; *vox clamantis in deserto*.

The present pamphlet of Dr. Serrurier's is a supreme effort to improve this sad state of affairs, a last appeal to the national

[1] A system of cataloguing introduced not long ago by Dr. Serrurier in the Leyden Museum, as far as I know not followed in any other ethnological museum, is what might be called the "Note Catalogue." Each object has an inventory number referring to a separate note on a slip of stiff paper, which contains, besides a small photograph of the object in question, a full description of it, and bibliographic indications relating to its origin, occurrence, use, &c. This system facilitates greatly the study of the objects.

representatives, the members of the First and Second Chambers. The granting of a considerable sum of money for the building of a new National Museum of Natural History at Leyden, a necessity long felt and perseveringly advised by its director—Dr. Jentink—furnished an occasion to bring the question once more before the public. What the result will be—museum or storehouse?—we cannot tell. If a man is not convinced after reading Dr. Serrurier's pamphlet, he will never become convinced.

"But whatever may be done"—Dr. Serrurier concludes his interesting paper—"every change, in this case, will be an improvement, for now the life of the museum is ebbing away. The time is near that it will sink into a lethargic sleep, the end of which will be death." H. ten Kate.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—Mr. T. I. Pocock, of Corpus, has recently been elected to the Burdett-Coutts Geological Scholarship. It is his intention, we believe, to devote himself ultimately to the science of astronomy, which he studied at Oxford under the late Prof. Pritchard.

Mr. E. A. Minchin has been elected to a Biological Fellowship at Merton College, and Mr. H. M. Vernon, of that college, has been elected to the Oxford Biological Scholarship at Naples.

Cambridge.—The council of the Royal Geographical Society offer in the present academical year a studentship of £100, to be used in the geographical investigation (physical or historical) of some district approved by the council. Candidates must be members of the University of not more than eight years' standing from matriculation, who shall have attended the courses given in Cambridge by the late or present University lecturer in geography.

The following awards in Natural Science were made at St. John's College on December 11:—K. C. Browning (Dulwich College), Foundation Scholarship of £80; E. R. Clarke (Tonbridge School), Foundation Scholarship of £50; O. F. Diver (Winchester College) and K. B. Williamson (St. Paul's School), Minor Scholarships of £50: A. A. Robb (Queen's College, Belfort), R. F. C. Ward (Epsom College), J. A. Glover (St. Paul's School), and G. D. M'Cormick (Exeter Grammar School), to various Exhibitions of £50 and under.

SOCIETIES AND ACADEMIES.

London.

Linnean Society, November 16.—Prof. Stewart, President, in the chair.—Mr. J. H. Veitch exhibited a large and interesting collection of economic and other vegetable products of Japan, recently brought by him from that country, and described the various uses to which different kinds of wood, fibre, grass, &c., were applied for domestic purposes, as also the way in which various seaweeds were collected and prepared for food.—Mr. A. G. Renshaw exhibited a remarkably large specimen of the giant puffball, *Lycoperdon giganteum*, which he had gathered at Catford Bridge.—On behalf of the Rev. Prebendary Gordon, the secretary exhibited a plant of *Veronica salicifolia* of New Zealand, found growing in Langland's Bay, Mumbles, Swansea, having been introduced by some chance.—A paper was then read by the Rev. G. Henslow, on the origin of plant structures by self-adaptation to the environment, exemplified by desert and xerophilous plants. The purport of this paper was to prove by a direct appeal to facts the probably universal application of Mr. Darwin's assertions, viz.: (1) that natural selection has no relation whatever to the primary cause of any modification of structure ("Animals and Plants, &c." vol. ii. p. 272); (2) that modifications of structure are due to the direct action of the environment (*fide* Darwin, Weismann, Spencer, &c.). This always results in "definite variations," by which Mr. Darwin signifies (3) that all, or nearly all, the individuals became modified in the same way ("Origin of Species," 6th ed., p. 106), and consequently (4) that "a new variety would be produced without the aid of natural selection" ("Animals and Plants," ii. 271, "Origin of Species," pp. 72, 175). Mr. Henslow showed (1) that all the species constituting the peculiar *facies* of a desert flora are the direct result of their climatic conditions; (2) that these peculiarities are in nearly all cases of the utmost benefit to the plants, such as the hardening of the tissues, the reduction of parenchyma, the minute size of the leaves, the dense clothing of hair, a thick cuticle, the presence of wax, storage of water tissues, &c. But (3) these features are just those which systematists utilise as descriptive characters of varieties and species. Mr. Henslow observed that by Darwin's assuming that "indefinite variations" which are characteristic of *cultivation* were equally so in *nature*, he reasonably required natural selection to correspond with artificial selection; but that assumption he believed to be erroneous. For experiments proved that by sowing seeds in a very different medium, *all* the seedlings vary in the same direction, viz. that of adaptation to the new environment, verifying Mr. Herbert Spencer's statement that "under new conditions the organism immediately begins to undergo certain changes in structure, fitting it for its new conditions." The conclusion is thus arrived at which is expressed in the title of this paper. The functions of natural selection therefore become limited, as follows: (1) The survival of the constitutionally strongest amongst seedlings; (2) delimitation of species by the non-reproduction of intermediate forms; (3) the geographical distribution of plants by self-adaptation. An interesting discussion followed, in which Prof. Reynolds Green, the Rev. Dr. Klein, Mr. Perry Coste, and others took part.

Zoological Society, November 21.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—The secretary read a report on the additions that had been made to the Society's menagerie during the month of October, 1893, and called special attention to an example of Goliath beetle (*Goliathus druryi*), the largest of known Coleoptera, obtained near Accra, and presented October 5, by Mr. F. W. Marshal, and to an adult female and a young of the Manatee (*Manatus americanus*), captured in Manatee Bay, Jamaica, and most kindly sent home for the Society's collection by Sir Henry A. Blake. Unfortunately the Manatees had reached the gardens in a very exhausted condition, and died soon after their arrival.—The secretary read an extract from a letter addressed to him by Mr. J. S. Mackay, of the Kangra District, Punjaub, relating to a young snow-leopard which he had in captivity, and exhibited some photographs of this animal.—Mr. Sclater exhibited and made remarks on a mounted specimen of an African monkey (*Cercopithecus albogularis*) belonging to the Leyden Museum.—Mr. W. B. Tegetmeier exhibited and made remarks on two hybrid pheasants, believed to be crosses between the common pheasant and the gold and silver pheasants.—A communication was read from Messrs. G. W. and E. C. Peckham, on the spiders of the family *Attidæ* of the island of St. Vincent, based on specimens collected in that island by the agency of the joint committee of the Royal Society and the British Association for the exploration of the Lesser Antilles. The series had been collected by Mr. Herbert H. Smith and Mrs. Smith, who had been specially sent to the island as skilled collectors by Mr. F. D. Godman, F.R.S.—A communication was read from Mr. P. R. Uhler, containing a list of the Hemiptera Heteroptera collected in the island of St. Vincent by Mr. and Mrs. Herbert H. Smith, with descriptions of new genera and species.—Dr. G. Lindsay Johnson made some observations on the refraction and vision of the eye of the common seal (*Phoca vitulina*).—Mr. Sclater read a paper on some specimens of mammals from Lake Mweru, British Central Africa, transmitted by Vice-Consul Alfred Sharpe, through Mr. H. H. Johnston, C.B. The specimens were referred to seventeen species, amongst which was a new monkey of the genus *Cercopithecus*, proposed to be called *C. opisthostictus*, and a new antelope allied to the waterbuck, which was named *Cobus crawshayi*, after Mr. R. Crawshay, who had first discovered the species.

Cambridge.

Philosophical Society, November 27.—Prof. T. McK. Hughes, President, in the chair.—The following communications were made.—The action of light on bacteria, by Dr. H. Marshall Ward. By throwing the spectrum on various bacteria suspended in films of agar, it is possible to obtain photographic records of the action of the various rays; because, after incubation, those spores or bacilli, &c. which are killed by certain rays remain invisible, whereas those still left capable of development render the agar opaque. The experiments show that those germs which are struck by the infra-red, red, orange and yellow, develop as rapidly as those not exposed to light at all. The action begins

as we leave the green and rises to a maximum in the blue-violet and violet, falling off as we pass into the ultra-violet. For the solar spectrum a heliostat and glass lenses and prism were used; for the electric spectrum a quartz train, and quartz covering the film. Even a thin plate of clear glass blocks out much of the effective region of the spectrum, and especially ultra-violet rays. The author recorded his thanks to Prof. O. Lodge, F.R.S., for kindly exposing the plates to the electric spectrum for him, with most successful results. The author also found that the water of the Thames, examined in August and October respectively, shows the following interesting results. (1) The number of bacteria per c.c. was distinctly smaller in the bright August weather than in the duller days of October, and differences were observable in the aspect of the colonies on plate-cultures. (2) Suspecting that this was concerned with light action, experiments showed that insolation not only kills off large numbers of the bacteria in the water, but in some cases shows its effects in diminishing the liquefying (*i.e.* enzyme action) power of certain forms, and even in altering their mode of growth, so that the aspect of the colonies is affected. These changes in aspect are not a mere matter of preventing or increasing the production of pigment, &c., but are due to effects on the *growth* of the colonies. As regards pigments, the author has examined a pigment of one of these river species, which, though so resistent as to bear solution in alcohol, evaporation and drying at 100 C., and re-solution, without apparent alteration, is destroyed in an hour or two on exposure to light.—On gynodioecism (third paper), with a preliminary note upon the origin of this and similar phenomena, by Mr. J. C. Willis. The experiments described in the two former papers have been continued, and have still further shown the very variable nature of the phenomena of gynodioecism. From the results, taken together with those of experiments upon dichogamy and cleistogamy, and the observations of other writers upon these subjects, the author is inclined to the conclusion that all these phenomena, together probably with androdioecism, andromonoecism, polygamy, dioecism, &c., are closely allied to one another, depending largely upon varying conditions of nutrition, these again depending on numerous factors, such as soil, climate, temperature, light, season of the year, moisture, and internal conditions in the plant itself. These factors acting together or separately, may call forth, in a marked degree, any of the above phenomena. In the most marked cases natural selection appears to have come into play, and the phenomena have become hereditary, but in many cases they seem to be only sporadic. A full review of the literature relating to these subjects is in preparation.

Paris.

Academy of Sciences, December 4.—M. de Lacaze-Duthiers in the chair.—Significance of the localisation of organs in the measurement of the gradation of plants, by M. Ad. Chatin.—Estimation of manganese oxides by oxygenated water, by Harry C. Jones.—On the profound deformations of the spheroid of Mars, by Dom Lamey.—On the observations made by M. J. Vallot on the summit of Mont Blanc in 1887, by M. Alfred Angot. From the barometric pressures and temperatures observed by M. Vallot on the top of Mont Blanc, and simultaneous observations made on the Säntis, Obir, and Puy-de-Dôme, and at Berne, Geneva, and Lyon, the height of the former may calculated. The values thus obtained range from 4810·4 m. to 4824 m. The true height is 4810 m., so that an interesting confirmation of Laplace's law is obtained. The temperature at the limit of the atmosphere has been calculated by Voeïkoff according to Mendelejeff's formula, which makes the temperature of the air a linear function of the pressure. The result obtained from numerous mountain observations is $-42°$. A combination of the Mont Blanc observations with those of the three mountain stations mentioned gives $-47°$, and with the three town stations $-45°$. Since these values are obtained from summer observations only, they are probably a little too low.—On the complex acids which are formed by molybdic acid with titanic acid and zirconia, by M. E. Péchard.—Researches on the constitution of the albuminoid materials extracted from the vegetable organism, by M. E. Fleurent.—On the stability and the conservation of dilute solutions of corrosive sublimate, by M. Léo Vignon. If a solution of sublimate of 1 grain to 1 litre of distilled water is left to itself for a few days at the ordinary temperature, it gives rise, in a period varying from one to three days, to a white precipitate whose quantity gradually increases. Quantitative measurements of the amounts of mercury thus precipitated under varying conditions gave the following results. When the solution was left in an open vessel, the percentage of mercury left in solution after seven days was 0·57, in a closed vessel 0·97, and 0·67 after 220 days. When colouring matters were added to the solutions, the corresponding numbers were, for fuchsine, 0·67, 0·97, and 0·77; and for indigo carmine, 0·76, 0·98, and 0·80, the latter therefore giving the greatest stability.—Discovery of abrastol in wines, by M. Sangle-Ferrière. This gives a method of finding whether abrastol, a new antiseptic for the preservation of wine, has been used in a given sample. It is the sulphuric ether of β-naphthol combined with calcium. The method utilises the decomposition ensuing when abrastol is heated with dilute H Cl, calcium carbonate, sulphuric acid, and β-naphthol being formed.—On the sterilisation of bread and biscuit on coming from the oven, by MM. Balland and Masson. This gives an answer to the question whether all dangerous germs which may have been contained in the water used for breadmaking, are destroyed during the process of baking. Experiments show that microbes in general are incapable of resisting the acidity of the dough and the high temperature of baking. Certain spores notorious for their stability are indeed capable of regaining their activity under favourable circumstances, but all pathogenic bacilli, especially those of typhoid and of cholera, are certainly destroyed.—Some chronometric data relating to the regeneration of nerves, by M. C. Vanlair.—On the termination of the motor nerves of striated muscles in the Batrachians, by M. Charles Rouget.—On some points relating to circulation and excretion among the cirrhipeds, by M. Gruvel.—On phosphaturic albuminuria, by M. Albert Robin. The constitution of the group of phosphaturic albuminurias, shows that the morbid entity known as Bright's disease, is often nothing but the anatomical complication of an anterior purely functional malady, and that, like a number of similar cases, the cure should begin at this anterior functional disorder.—Parasites in cancer, by M. G. Nepveu.—The shell cavity of the Philinidæ, by M. P. Pelseneer.—On a new gregarine of the Algerian Acridians, by M. L. Léger.—On the exchanges of carbonic acid, and oxygen between plants and the atmosphere, by M. Th. Schlœsing fils.—Observations on the constitution of the membrane in mushrooms, by M. L. Mangin.—On the primary strata of Saint-Pons (Hérault), by MM. P. de Rouville, Aug. Delage, and J. Miquel.—On the Triassic and Jurassic formations of the Balearian Isles, by M. H. Nolan.

Berlin.

Physical Society, November 3.—Prof. du Bois Reymond, President, in the chair.—Dr. Rubens discussed the experiments of Righi, who had succeeded in obtaining Hertz's oscillations of much smaller wave-length than had hitherto been found possible. Whereas the shortest waves obtained by Hertz were 55 c.m. long, and those by Döppler 20 c.m., Righi had produced waves only 7·5 c.m. in length, and had repeated all Hertz's experiments in a much more convenient form. Rubens had somewhat modified Righi's experimental arrangements, and produced waves 10 c.m. long, which he intended to submit to further investigation.

November 17.—Dr. O. Fröhlich explained a generalised form of Wheatstone bridge, and a series of applications of the same for theoretical and technical purposes. Dr. Blüme demonstrated a form of apparatus for showing refraction suitable for use in schools, giving accurate results to the third place of decimals with very little practice.

Physiological Society, November 10.—Prof. du Bois Reymond, President, in the chair.—Dr. Gumlich gave an account of feeding experiments made on dogs with nucleic acid, which showed an absorption of this substance by the animal organism. The phosphates of the urine were increased, as also the nitrogen of its extractives. There was no increase of uric acid.—Dr. Goldscheider made further communications on leucocytosis. His experiments, carried on in conjunction with Dr. Jacob, had shown that after the injection of hemialbumose, or extract of spleen, and other substances with similar action, there is a diminution (hypocytosis) in the number of leucocytes, followed by a rapid rise in their number up to the normal and then to a permanent increase above the normal (hypercytosis). When the active substance was injected into the jugular, it was found that during the brief period of hypocytosis the capillaries of the lungs were abnormally filled with leucocytes. Later on, there was a still further increase in this region at the time of increase of leucocytes in the blood generally. By using smaller doses of the active substance the stage of hypocytosis could be lessened

or even entirely suppressed, leaving only the stage of hypercytosis.

November 24.—Dr. Katzenstein gave an account of experiments on the median pharyngeal nerve. In the rabbit this nerve gives off branches to the cricothyroid muscle, whereas in the monkey, dog and cat no such connection can be made out, either anatomically or physiologically. Prof. Munk made some remarks, in connection with these experiments, on Prof. Exner's belief in the existence of a median pharyngeal nerve, which could at most only be admitted in the case of the rabbit. Prof. Zuntz described a new method of measuring the amount of the circulating blood and the work done by the heart. It depends on the fact that as long as the peripheral resistance is constant, blood-pressure is dependent on the volume of blood driven into the aorta by the left ventricle. When the heart is inhibited by stimulation of the vagus the blood-pressure falls, and if now a volume of blood is injected into the aorta sufficient to raise the pressure again to the normal, then this volume must be equal to that which the heart ordinarily drives into the arterial system. The method had shown itself to be reliable in experiments made on dogs, and had already yielded some interesting results relating to the circulation, which will be further investigated.

New South Wales.

Linnean Society, October 25.—Prof. David, President, in the chair.—The following papers were read:—On Polycercus: a proliferating Cysticercoid parasitic in certain earthworms, by Prof. Haswell and J. P. Hill.—Some points in the anatomy of the monotreme scapula, by Prof. Wilson and W. J. Stewart McKay.—Notes on the family Brachyscelidæ, with descriptions of new species, Part III., by W. W. Froggatt.—On some new genera of nematode worms found in Port Jackson, by Dr. N. A. Cobb.—On recently observed evidences of extensive glacier action at Mount Kosciusko Plateau, by R. Helms.—Contributions to a revision of the Tasmanian land mollusca, by H. Suter.—Notes on the occurrence of a species of Plecotrema and other species of mollusca in Port Jackson, by Dr. J. C. Cox.—On the distribution of little-known mollusca from Polynesia and Australia, with their synonyms, by John Brazier.—Dr. Cox exhibited a fine specimen of the herring *Elops saurus*, Linn., purchased in a Sydney fishmonger's shop, and believed to have been captured off Broken Bay; the species is occasionally taken in Port Jackson, though it is more properly an inhabitant of tropical seas. He also showed a piece of timber in an excellent state of preservation supposed to be red gum, a portion of a tree encountered in sinking a shaft in the bed of the river during the building of the bridge at Echuca; the specimen was forwarded to him by Mr. A. P. Stewart, of Hay, N.S.W. Dr. Cox also showed specimens of the shells referred to in his paper, and a very fine example of *Voluta manilla* from Tasmania.—Mr. Froggatt exhibited a fine series of mounted galls and coccids in illustration of his paper, including a new Brachyscelid collected by Mr. A. Roxburgh at Cobar, and representatives of several new species of Opisthoscelis.—Mr. North exhibited a set of eggs consisting of three eggs of *Collyriocincla harmonica* and an egg of *Cacomantis pallida* collected on the Woolli Creek on the 19th inst. The cuckoo's egg was deposited on the 17th inst., when the nest contained but two eggs of the Collyriocincla. This is the only occasion he had known the egg of any cuckoo to be found in the nest of the Harmonious Thrush. Mr. North also communicated a note in which he pointed out that the blue wren (*Malurus cyaneus*) is developing a protective habit against the cuckoos which intrude their eggs upon it, as he had found in several instances that the intruder's eggs were covered with a layer of nest material; a parallel instance has been recorded by Messrs. Sclater and Hudson in their "Argentine Ornithology."—Mr. Mitchell, of Narellan, contributed a note on the occurrence of a fossil at Stockyard Mountain, Jamberoo, bearing a strong resemblance to Lepidostrobus and Halonia; and of certain scales at Glenlee, referable, in his opinion, to one or other of the genera Lepidostrobus or Sigillariostrobus; also of a species of Pterophyllum, at Kenny Hill, near Campbelltown.—Mr. A. M. Lea showed a small collection of insects which inhabit ant and termite nests, including a dipterous insect (*Microdon variegata*), one of the Micro-lepidoptera at present undetermined, both from Sydney; and of coleoptera, two species of Pselaphidæ from Tamworth and Inverell, Anthienus sp., from Sydney, Lagria n.sp., from Coolamundra and Queanbeyan, and a fifth species (g. et sp. indet.).—Mr. Brazier exhibited for Mr. T. Steel three aboriginal stone axes, one with a groove for hafting, from the Herbert River, said to have been found at a depth of thirty feet in sinking a well; a second from the Tweed River, being a simple adaptation of a flat water-worn stone by grinding the thinner end; the third from Harrow, Victoria.—Mr. Fletcher exhibited for Mr. G. L. Pilcher, of Rockhampton, an undescribed longicorn, and two of the mud nests of one of the solitary wasps (*Eumenes Latreillei*, Sauss.), together with specimens of the wasp and of a species of *Chrysis* which, like members of the same family elsewhere, plays the part of cuckoo; and he communicated a note giving particulars of the mode of construction of the nests exhibited, and of the habits of the maker and of the attendant intruder.

BOOKS and SERIALS RECEIVED.

Books.—Elementary Trigonometry: H. S. Hall and S. R. Knight (Macmillan).—A Theory of Development and Heredity: H. B. Orr (Macmillan).—Natural Value F. von Wieser, translated (Macmillan).—The Vault of Heaven: R. A. Gregory (Methuen).—A Journey through the Yemen: W. B. Harris (Blackwood).—Chinese Central Asia, 2 Vols.: Dr. H. Lansdell (Low).—The Dispersal of Shells: H. W. Kew (K. Paul).—A Text-book of Physiological Chemistry: Prof. O. J. THURSDAY, DECEMBER 21, 1893.

THE TOMBS AT BENI HASAN.

Beni Hasan. Part I. (Published under the auspices of the Egypt Exploration Fund.) By P. E. Newberry and G. W. Fraser. (London: Kegan Paul, 1893.)

IN the handsome volume which lies before us the Egypt Exploration Fund publishes the first part of an "Archæological Survey of Egypt," which it proposes to issue under the direction of Mr. F. L. Griffith; and we believe that it will be generally admitted the site selected for description and illustration in the first part of the projected work could not have been better chosen. We are also very glad to see that the committee has changed the scene of its excavations from Lower to Upper Egypt, for there it is moderately certain that excellent results will accrue to the archæologist and Egyptologist. It must not be thought for a moment that we wish to underrate the value of the excavations which the Fund has made in the Delta, but it must be said that in the days, now past we hope, when sentimental Egyptology was more rampant than it is now, too much time and money were spent in the endeavour to bring to light "proofs" of the truth of the Bible narrative which could not exist, and in twisting evidence to suit the fancies of enthusiastic *dilettanti.* We admit that in the Delta these things are "in the air," for the land of Goshen lieth there, and the sites at which the Israelites are supposed to have halted must be sought therein, and the *yam sûph*, or "sea of reeds," must border it in some part; but in Upper Egypt we are face to face with the mighty monuments of some of the best periods of Egyptian art and sculpture, and we are free from the influence of the heterogeneous mixture of peoples in the Delta, and in the everlasting hills which fringe the banks of old Nile we have the remains of a nation which could boast of a hoary antiquity, even before Joseph came into Egypt. The spot chosen for the new scene of labour by the Egypt Exploration Fund is Beni Hasan, probably better known as Jebel Beni Hasan, which forms a link in the long chain of cliffs which bound the eastern side of the Nile valley, and for which we may look on the map between Minyeh and Roda, a little more than 150 miles south of Cairo. Here, high up in the rock, are hewn two ranges of tombs, which are approached by a sloping path, at the top of which is a terrace whereon all the large tombs open. Of the thirty-nine tombs at Beni Hasan, twelve are inscribed, and of these eight are of governors of the nome wherein they are situated; two are of princes, one is of the son of a prince, and one is of a royal scribe. In one range—the northern—are thirteen tombs, and in the southern are twenty-six. Speaking broadly, it may be said that both ranges were hewn during the twelfth dynasty, or about B.C. 25 0. Of the twelve inscribed tombs six may be dated with a fair amount of accuracy; one (No. 14) bears the name of Amenemhāt I., and another was probably hewn at the end of his reign; No. 2 belongs to the reign of Usertsen I., and Nos. 3, 4, and 23 we must place in the reign of Usertsen II. Concerning the remaining six, we need have little doubt as to their age, for the position of some of them indicates that they belong to the period anterior to the reign of Amenemhāt I.

Considered historically, the tombs of Ameni-Amenemhāt and Khnemu-hetep are of the greatest importance, for they afford us some insight into the life of high officials in those days, and incidentally record some interesting historical facts. In the reign of Usertsen I. Ameni held the high rank of hereditary prince, and he was chosen by his royal master to make three expeditions into Nubia and Ethiopia; on the first occasion he accompanied his king; on the second he set out with the royal heir at the head of four hundred men, and brought back the appointed tribute; and on the third, he marched at the head of six hundred men. In quaint, characteristic language this worthy nobleman paints his own character, and says: "I wronged not the daughter of a poor man, I oppressed not the widow woman. I was not hostile to any farmer, I stood not in the way of the cattle-keeper, I levied no men for my works, there was no beggar round about, neither felt any man hunger in my days. In the season of famine I ploughed the land of the nome, north and south, I saved the life of its people, and I provided food, so that there was no man hungry therein. I gave to the widow the same as to the married woman, and in this respect I treated the younger as the eldest son. When, in after years, there were abundant Niles, and wheat and barley were plentiful, I did not claim payment for what I had given in the previous years." The most interesting text in the book, however, is that in which Khnemu-hetep, a feudal chief, records the chief events of his life, and the high services which he had rendered to his king. He was the son of Nekhera, and of the daughter of a princess called Baket, and he held the office of governor of the Arabian desert, and *utcheb* priest of Horus and Pakhet; the king, Amenemhāt II., granted unto him the inheritance of his father and mother in Menāt-Khufu, and his property lay on each bank of an arm of the Nile, or of that river itself. As a landowner, he gave great attention to the adjustment of the boundaries of each city in the nome, and his fair and upright dealing in this respect gained him great favour in the sight of all men. The king promoted him over the heads of all his nobles, and conferred favour after favour upon him; his sons, Necht and Khnemu-hetep, who had been born to him by the lady Khati, were each raised to the rank of *Smer uat.* Following the example of his father Nekhera, the son of Sebak-ānkh, who from his earliest childhood had held the highest place in the king's favour, Amenemhāt built a tomb, upon which are his own name, and that of his father, and it is to the inscription which he caused to be engraved upon it, under the direction of the architect Baqet, that we owe our knowledge of the life and times of this trusted official. The hieroglyphic text of the inscription has been published several times, but Mr. Newberry has succeeded in correcting several errors, one of the most important being in line 12. There is no doubt that this edition of the text is the best hitherto published. But hieroglyphic texts are, in the main, only useful for Egyptologists, and they form, after all, but a very small part of the book, which owes its chief attraction to the large number of beautiful plates which are in it. In these we

find depicted representations of all the chief scenes which are found in the first fourteen of the tombs that form the subject of the part before us, and it would be difficult to speak too highly of their excellence. The reader who has seen the originals will have them brought again vividly before his mind, and he who has not seen them may rest content that he has under his eyes faithful copies of the paintings reproduced in soft and pleasing tints. The subjects for the coloured plates are well chosen, and we believe that they will be generally admired. Altogether, the life of what we might describe as an "Egyptian feudal baron," enjoying high favour with the king, is most thoroughly depicted; the periodic war waged against the blacks in the gold-producing countries, the chase, to keep the body sound and the limbs supple, and the keen personal superintendence of all agricultural operations, whereby the evil results of "absentee landlordism" was done away with, filled the life of these old lords of the soil, who fondly hoped to live in the next world as they lived in this. When we consider the state and luxury in which they lived, and the large households which they maintained, it is not difficult to understand why Egypt was always an object of plunder by neighbouring nations.

Before we end our brief notice of this most interesting book, we must call attention to the hideous system of transliteration which has been adopted throughout; but we are wrong in calling it "transliteration," for that is intended to help the poor reader, who is not an expert, how to pronounce; but this is not, and is only meant to indicate what Mr. Griffith imagines to be the proper way of representing Egyptian characters in English letters. Studies in systems of transliterations are excellent gymnastics for experts, but the non-expert resents the constant changes which are being thrust upon him; and no surer plan of alienating the interest of the general public can be found than that of setting out in a work which is paid for by the general public, and is meant for all readers, a system representing hieroglyphics in English letters, which is both unnecessary and difficult; moreover, we submit that the transliteration which Birch and Lepsius formulated is easy, and at the same time sufficiently correct for all practical purposes.

A NATURE LOVER'S CORRESPONDENCE.

Letters to Marco. By George D. Leslie, author of "Our River." (London: Macmillan and Co., 1893.)

MR. LESLIE has published a good book with an unpromising title. It contains thirty-seven letters written to an old friend, H. Stacy Marks, R.A. The first of these is dated October 4, 1885; the last, March 6, 1893.

Both the author and his friend have attained to eminence as painters, but there is no word in the book which alludes to their professional careers; and but for an occasional grumble that a picture is not going smoothly, no one would guess that the letters were written from one artist to another.

The interest of the correspondence centres upon mutual associations connected with the banks of the Thames, where they wandered together in days gone by, observing nature, sketching her, and nourishing their youth with aspirations, many of which they have lived to realise.

That was in very early days, when name and fame were still behind the clouds of morning, and when they used to leave London annually with the expressed intention of "improving the quality of the British kit-cat," which was still in an unregenerate condition.

As the interest of an artist's career lies in his struggles, and as the annals of success make commonplace reading, we can be grateful that all allusion to professional matters has been left out, though we might have been glad to have more artistic observations, such as that of the black rook flying away with a golden walnut in his mouth.

One palpable realised ambition is the pretty property which Mr. Leslie has bought at Wallingford, from which he writes to his old friend, describing the condition of their old haunts, and chatting in a desultory way about nature in general.

As Mr. Marks is an ornithologist, there is a great deal about birds. He observes their ways, and describes the kingfisher hovering over the water, the terns hawking on the shallows, and the poor swallows during a frost cuddling up together to keep warm; and what is a great comfort, he kills nothing. He is not a sportsman, and not being a naturalist he does not want specimens for dissection; he merely observes with loving watchfulness; in hard winters he scatters food to mitigate the lot of his feathered friends, and it is absolute grief to him when his children bring a poor fledgling which they have captured. This is the great charm of his book, which probably adds little or nothing to our knowledge of natural history; indeed, its method is the reverse of scientific, and its originality consists in the persistent way in which the author discerns human attributes in birds. They are to him a little people, whose customs and ways of thinking he studies attentively. The robin comes to him to sing a "conciliating song," the blackbird is "proud, vain, and impudent," and the sparrow is "bold, but he knows that he is only tolerated"; and these things are evidently not stated with any conscious or intentional metaphor, but in perfect good faith. The author, in fact, is an amiable enthusiast, who loves nature with his whole soul; and when the contemplation of birds, beasts, flowers, and fruit has worked him up to a state of enthusiasm, rushes home and writes to his friend to tell him what he thinks about them.

We do not feel in a position to dispute the theories which he occasionally propounds, such as that the young shoots on a hedge are kept in their place and supported by cobwebs, that darkness is favourable to the growth of plants and babies; on all these matters he speaks with more authorlty than we can pretend to. All we can venture to say is, that "si non e vero e ben trovato"; and his theory of darkness seems to explain the unfolding of a sycamore shoot, though he gives no instance of its operation in the case of the young of the human species.

The contemplation of all things in nature—birds, beasts, and fishes, reptiles, insects, and molluscs, inflames Mr. Leslie to a rapture of affection; and when the fit is on him, he can find extenuation even for snails and sparrows, whereby he soars into a lofty and rarified region of

charity and benevolence, into which we find it impossible to follow him.

There are many amusing descriptions and playful passages scattered through the book, such as the friendship of the donkey and the dirty drake who disliked cold water; and the droppings of the reindeer, which the author spread round his Iceland poppies because he thought it might amuse them; and it is also very pleasant reading on account of its evident sincerity and absence of affectation, of which the following is a fair example.

The author describes the snails in his garden: "the common 'tabbies,'" he says, "have already begun to hibernate, but the bushes are covered with a small flat kind." A less conscientious and more pretentious writer would inevitably have made a shot at their generic and specific names, and given us the words "Helix aspersa" and "Helix nemoralis" in brackets; but Mr. Leslie very wisely makes no pretensions to be considered a naturalist, though he knows more of the aspect of organic life than many an authority on comparative anatomy; his knowledge is that of Götz von Berlichingen, who "knew every pass, pathway, and ford about the place, before he knew the name of village, castle, or river," and he seems thoroughly to sympathise with the sentiments of Shakespeare's "Biron":—

> These earthly godfathers of heav'n's lights
> That give a name to every fixed star,
> Have no more profit of their shining nights
> Than those that walk and wot not what they are.

The accuracy of Mr. Leslie's observation is shown by the illustrations which he has scattered through the volume; some of these are extremely beautiful, such as the "Bird's-eye View of a Swallow," "The Fruit of Rosa Rugosa," and "Flight of Starlings and Rooks," as is also the frontispiece, representing his house at Wallingford.

This book we can confidently recommend for its tonic properties. To the great world of men and women given over to satiety and boredom it cannot but be salutary, by pointing out what a world of enjoyment, what a peaceful and engrossing occupation for leisure, lies open to all of us, outside our own doors, and the only price we have to pay for it is to take the trouble to use our eyes.

OUR BOOK SHELF.

A Text-book of Heat. The Tutorial Physics, vol. ii (Univ. Corr. Coll. Tutorial Series.) By R. Wallace Stewart. (London: W. B. Clive, 1893.)

NOT long ago we had occasion to say a few words about the books which have appeared from the pen of this author, and we then stated our belief in him as a writer whose clearness of explanation and conciseness of language would render him popular among students of physics. In the volume now before us, which is devoted simply to the one branch of this large subject of physics—heat—we may again apply the same remarks to the treatment of the subject, the author stating with all clearness and necessary accuracy the various laws, and showing their practical application by means of appropriate examples. In the descriptions of the experiments, as, for instance, in those for determining the absolute expansion of mercury, the object of the experiment in question, the end to be obtained, and the different means of attaining it, are especially emphasised, and the diagrams aid the reader in grasping a clear idea of the arrangement of the apparatus employed. At the end of each chapter, under the heading "calculations," are brought together all the formulated expressions of the laws deduced in the one preceding—a very useful arrangement for a short revision of the subject. The concluding chapter deals with the application of graphic methods to the results of experiment, and this part of the subject is one of great importance, although generally omitted in text-books. The work, as will have been noticed from the heading, is published in the Tutorial Series, and is a most useful addition to it.

The Industries of Animals. By Frédéric Houssay. (London: Walter Scott, Ltd., 1893.)

THIS—the twenty-third volume of the Contemporary Science Series—is an English edition of a good book. It is not merely a translation, but a revised and enlarged edition, to which numerous bibliographical references have been added. By this addition the work has gained considerably in value; for such references are not only useful to the student who desires to increase his knowledge of any matter broached in the book, but they also furnish a means of estimating the weight of the many stories of animal intelligence and instinct contained in it. The first chapters of the book deal with those industries of animals of which the object is the search for prey. These industries are necessarily connected with protective effects providing for the immediate safety of the individual. A number of examples are then given, to show that "social species unite for the common security the forces and effects which they can derive from their own organs." The art among animals of collecting provisions, of domesticating and exploiting flocks, and of reducing their fellows to slavery, is well described, and, finally, the series of modifications which the dwelling undergoes is investigated.

Except in one or two places, the translation reads very well. Forty-four figures illustrate the text, most of them adapted from that great repository of facts in natural history—Brehm's *Thierleben*. Altogether the book is very pleasant reading, and it contains a large amount of matter of interest to all students of animal skill and intelligence.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Flame."

IN NATURE for November 23, p. 86, under this title, there appears an account of a lecture delivered by Prof. Smithells to the British Association on September 15, in which he brings before the Association those fascinating experiments with which his name has lately become identified. The apparatus by means of which Prof. Smithells draws the "inner cone" of a flame away from the "outer cone," and which he describes as *an appliance for dissecting the flame*, or *the cone-separating apparatus*, is now quite familiar to most. By means of it a regulated stream of air is admitted along with the burning gas, until a portion of the flame recedes down the tube, and is arrested in its downward movement at the top of an inner tube, where the issuing gases are moving upwards at a slightly greater rate.

In all cases Prof. Smithells calls this descending flame the *inner cone*, and regards the remnant of the flame that remains at the top as the *outer cone*. It would appear to follow, therefore, that if, by means of the "cone-separator," a flame can be so dissected, it must have originally consisted of two cones.

Prof. Smithell describes the flames of hydrogen and of carbon monoxide as being of the simplest construction; it being out of the question that any complications can arise in the combustion of hydrogen to water, and of carbon monoxide to

carbon dioxide. These flames are therefore described by him as being "simply a hollow conical sheath of pretty uniform character." This is undoubtedly a true description; neither of these flames presents the appearance of double-coned structure which is seen in such flames as cyanogen, carbon disulphide, ammonia, and others; and it is hardly possible that in a hydrogen or carbon monoxide flame there can be two distinct areas or cones in which different chemical processes are going on. It occurred to me that it might throw some light upon the real value of this cone-separating apparatus as an appliance for dissecting flames, to try its effect upon the single-coned flames of carbon monoxide and of hydrogen. When air was cautiously admitted into these gases, as they burned at the top of the tube, I found that the flame travelled quickly right down the tube, and did not stop at the narrower tube when the upward rate of movement was greater, and did not appear to leave any remnant at the top of the wider tube. I have no doubt but that Prof. Smithells has made this experiment, and with a similar result.

I have found, however, that by a slight modification of the apparatus, it is quite easy to drag down an inner flame from either the flame of carbon monoxide or of hydrogen. In order to do this, all that is necessary is to provide the top of the inner and narrower tube with a cap made of fine wire gauze, either copper or platinum. When this small addition to the original apparatus is made, and the experiment with carbon monoxide is repeated, it will be seen that as air is gradually introduced a portion of the flame descends the tube and sits quietly upon the wire gauze, and, in spite of the flame-extinguishing power of the carbon dioxide it there generates, a remnant of the original flame remains feebly burning at the top. In the case of hydrogen a similar result is obtained, a portion of the flame descending to the gauze, where it burns with a pale blueish flame, while the remnant burns freely at the top. These experiments show that whatever is the structure of the flame, a part of it can be torn away from the rest by the regulated introduction of air: that in order to divide a flame by this method it is *not* a necessary condition that the flame should consist of more than one "cone," or, in other words, that there should be two distinct areas of combustion. If, therefore, a "simple" flame like that of hydrogen, consisting of a single cone of uniform character, can be divided, the fact that other and more complex flames can also be so divided, does not seem to throw much light upon their structure. As soon as sufficient air has been admitted into a flame, of whatever burning gas, to produce a certain volume of an explosive mixture whose rate of explosion exceeds the rate of efflux of the gases, that exploding mixture will become detached from the remainder of the burning gas, and travel back down the tube. In the case of hydrogen, where a very wide margin exists within which mixtures of this gas and air are rapidly explosive, the admission of a very small quantity of air is sufficent to form such a mixture, and so drag down a comparatively small portion of the entire flame. In the space between these two flames there can only be water vapour as the product of combustion, atmospheric nitrogen, and the excess of hydrogen. The lower flame is a burning mixture of air and hydrogen in which an excess of air is taking part in the combustion, and represents a condition of things certainly not far removed from, if not identical with, the old phenomenon of air burning in hydrogen. It is difficult to see in what way the separation of other flames differs from this.

I have no doubt that everyone who has read the account of Prof. Smithell's lecture will have been struck, as Dr. Armstrong was, with the manner in which the classical researches of Dr. Frankland are brushed aside, and the difficult question as to the true causes of the luminosity of flame is settled by an appeal to the "opinion of the majority."

Without touching the question as to whether or not solid carbon is actually precipitated during the decompositions that are going on in a coal-gas flame, the recent experiments of Prof. Lewes leave no room for doubt that the first stage in the process of decomposition and condensation that goes on, is the production of acetylene, which is formed during the passage of the gas through the inner dark area of the flame, where no combustion is going on; that is to say, where the hydrocarbons are being simply strongly heated, but are not burning. This fact seems to have an interesting bearing upon some of the peculiarities exhibited by the well-known flame of air burning in an atmosphere of coal-gas. In this flame the air is in the inside, and the hydrocarbons upon the outside; it is in effect an ordinary coal-gas flame *turned inside out*. The formation of acetylene, instead of taking place within the flame, as in the usual conditions, in which case it has to pass through the heated area where it is further decomposed with probably the precipitation of carbon, is now produced upon the outer surface or periphery of the flame; it therefore largely escapes combustion or decomposition, and passes into the coal-gas atmosphere with which the flame is enveloped. Hence the flame is non-luminous, and hence also this constitutes the ready method for obtaining large quantities of acetylene first devised by Prof. McLeod. I am not aware that it has ever been noticed that during the combustion of this non-luminous flame there are produced, besides acetylene, other hydrocarbons of much greater density. That this is so is evident from the fact that when the flame has been allowed to continue burning for a length of time, the glass vessel in which it is contained becomes coated with a brown tarry film. This non-luminous flame of air burning in coal-gas can be rendered luminous by a simple device. If the vessel employed in which to burn it be an ordinary bulb-shaped paraffin lamp chimney, it will be seen that when the flame is in the middle and wide portion of the chimney it is non-luminous; if, however, it be thrust up into the narrow part, it at once shows signs of luminosity: the acetylene under these circumstances is reflected back into the flame, which, aided no doubt by the radiated heat from the glass, causes the luminosity. If the supply of air be regulated, the flame may be caused to curl over upon itself, whereby very beautiful vortices are obtained, in which Heumann's floating particles are well seen. There is an old experiment in which two flames of air in coal-gas are placed side by side, and so arranged that at will they can be caused just to impinge upon each other. At the point where they touch a small luminous area is seen to appear, the luminosity being probably due to the same causes.

G. S. NEWTH.

I AM unable to understand how Prof. Smithells can in any way suppose that I either have, or possibly could, cast any imputation on his honesty, "scientific" or otherwise; and I fail also to understand what has given rise to the impression, unless it be that the opening sentence of my letter—which I intended should convey a compliment—has been turned round and a meaning given to it which I never contemplated, and which it cannot fairly be made to bear.

I have always regarded NATURE as a journal which is willing to afford a fair field for the consideration of scientific problems, but the last place in which to raise, let alone discuss, personal questions. By publishing his lecture in NATURE, Prof. Smithells directly challenged criticism, and the only object and intention of my letter was to challenge the validity of certain of his arguments. That he should have taken the view he has, is to me a matter of deep regret. He has now stated his position very clearly, and the passage that he has been good enough to quote from my letter to Sir G. G. Stokes sufficiently defines mine. I fear that we must agree still to differ; evidently we look at these matters from very dissimilar standpoints.

HENRY E. ARMSTRONG.

The Postal Transmission of Natural History Specimens.

AT page 100, *ante*, you reproduce a circular letter, sent out by the Academy of Natural Sciences of Philadelphia, on this subject, the object of which is the very laudable one of establishing an international rate of postage for natural history specimens, based on that charged for *bona fide* trade patterns and samples. It is therein stated that the United States Post Office Department recently proposed to the countries comprised within the Postal Union a modification of the rates in favour of a charge so based, but that the Governments of very many of them declined to consider the proposal, and in the list there given Great Britain is included. No precise date for this refusal on the part of the British postal authorities is given, but presumably the date is not precisely recent. Early in 1891, several of our Natural History Societies agreed to approach the British postal authorities on this point, and a letter was addressed to the Secretary of the Post Office (the late Sir S. A. Blackwood) by Lord Walsingham, on March 18, 1891. A reply (which I have before me) to that letter, from Sir S. A. Blackwood, is dated April 13, 1891, and is published in the Proceedings of the Entomological Society of London, 1891, p. 14 (and probably elsewhere). An extract from the letter is to this effect:—"Your

lordship will no doubt be glad to learn that so far as this Department is concerned, scientific specimens sent by sample post, and addressed to places abroad, will not be stopped in future; but I must state that this Department cannot guarantee the delivery of such specimens abroad, inasmuch as they do not come within the definition of sample packets as prescribed by the Postal Union." I may add that within the last month I have, on two occasions, sent specimens abroad by sample post with perfectly satisfactory results.

All naturalists will feel grateful to the Academy of Natural Sciences of Philadelphia for agitating in this matter. But it is to be regretted that the United States Postal Department should, in another way, continue to maintain a barrier against cheap transmission and interchange of specimens. The sample post can, in any case, only be used for small packets, but larger packages can now be sent to nearly all foreign countries by parcel post, the introduction of which was an inestimable boon. The United States Government stands almost alone in persistently refusing to co-operate in this respect. It is not for scientific men to inquire into what contracts that Government may have entered into with private carrying companies, or how far it may be influenced by hyper-protective susceptibilities; they can only regret the facts, and deplore the result.

Lewisham, December 8. R. McLACHLAN.

"Geology in Nubibus."—Mr. Deeley and Dr. Wallace.

MR. DEELEY will not have anything to say to ice conveying thrust *as a solid body*, which has been the sheet anchor of glacial geology for many a decade. He also repudiates Dr. Wallace's notion that regelation can in some way act as a compensating element when crushing supervenes in ice, and thus enable it under crushing pressure to convey thrust. So far so good.

Mr. Deeley, however, bids me turn to ice acting as a viscous body, a subject on which I have written a great deal in my recent book, which he does not seem to have seen.

There are two ways in which we can conceive a viscous body flowing on a flat plain: (1) by pure fluid, or what is commonly called hydrostatical pressure, in which the upper layers move up and down, and the lower layers alone have a horizontal motion; (2) by its particles rolling over each other. The former depends, of course, entirely upon the difference of level of two connected parts of the mass under consideration; the latter depends upon the slope of the upper surface of the fluid.

I contend, as Forbes contended, that in the case of a body so slightly fluid as ice, motion by hydrostatic pressure is practically impossible. The consistency and mutual support of the parts prevent the indefinite transmission of pressure in this way through ice, and nowhere have I seen or heard that in detached masses of a glacier cut off at either end by crevasses the ice rises in one place, and sinks in another, or that the walls of these ice rifts or the perpendicular ice walls in the arctic and antarctic regions or in scarped icebergs bulge out below in the slightest degree, as must happen if ice were to move in this method.

Forbes' experiments and measurements and patient examination of the problem proved that ice as a viscous body moves in fact by its layers rolling over each other, and that this motion is differential, being greatest at the surface and in the middle, and least at the base and sides of a glacier.

It is quite true that the rate of this motion on a flat plain would depend theoretically on the slope of the upper surface of the ice. It is established by experiment, however, that such motion is very largely confined to the surface layers, and when we approach the nether layers the motion quickly slackens, owing to the internal friction and drag of the ice particles. Even on inclined beds, glaciers have sometimes been found frozen to the ground. The evidence of a large number of observers is conclusive, that as glaciers reach the level ground, the motion, even of their upper layers, gradually stops. The masses of ice that collect on the flat Siberian Tundras do not move at all, nor do the thick horizontal ice beds examined by Dall in Alaska. Argument, experiment, and observation are therefore entirely against Mr. Deeley, upon whom the burden of proof rests. Perhaps he will explain what are the conditions under which he conceives his ice sheets to have been formed, to have been maintained, and to have moved. Mr. Wallace confesses that he does not like to face these mechanical issues, which are presupposed in all his reasoning. This is assuredly building on a quicksand, which is not a profitable experiment. He cannot be serious, either, in arguing that because I believe in Charpentier's view that the Alps were formerly higher, and consequently nursed bigger glaciers, I am therefore committed to Ramsay's extravagant notions, repudiated by nearly all explorers of glaciers, that the lakes of Geneva and Lucerne were dug out by ice. Charpentier's method, in such a case, would have prompted him to first prove the capacity of ice to do the work, and most people will agree that in a scientific argument this method is alone fruitful. H. H. HOWORTH.

30 Collingham Place, Earls Court.

The Viscous Motion of Ice.

Is not Sir H. Howorth wrong in assuming that there is no transmission of hydrostatic pressure in ice? Certainly Forbes was of opinion that such transmission existed, and was necessary to explain the remarkable parallelism between the motion of ice and of viscous fluids. It is a question of scale. Even a cup of treacle will not flatten out indefinitely; still less will a barrel of pitch; but I have no doubt a cubic mile of ice would flatten out, but to what extent is a question for calculation, not for dogmatic assertion. Unfortunately the first requisite of such calculations is wanting, as no determination of the coefficient of viscosity exists. Canon Moseley's experiments are clearly out of court, and in the interesting experiments of Mr. Coutts Trotter in 1883, the length of the portion of ice which took part in the shearing motion is not given.

May I add that the paragraph in Sir H. Howorth's letter of November 23, in answer to Mr. LaTouche, is distinctly erroneous so far as our limited evidence goes.

If Sir H. Howorth will draw to scale the observations of Prof. Tyndall at the Tacul on the side of the Mer de Glace, or those of Prof. Forbes, given on page 554 of his own book, he will see that while the velocity of the ice is greatest at the surface, the viscous yielding or differential motion is greatest at the bottom; and the curve into which a vertical line in the ice is thrown by the motion, is always convex towards the direction of motion, is relatively flat above, and strongly curved towards the base. This is exactly what we should expect on the viscous hypothesis, and justifies the application of hydrodynamical treatment to the problem, if only the necessary data were to hand.

19 The Boltons, S.W. JOHN TENNANT.
December 12.

Chemistry in Space.

IT may be of interest to your readers to know that the idea of the arrangement of atoms in space, which is looked upon as quite a modern one, is clearly put forth by Wollaston in his paper entitled "On Super-Acid and Sub-Acid Salts" (Phil. Trans. vol. xcviii. 1808, pp. 96–102).

He discusses the constitution of the two oxalates of potash; and I make the following extracts, but must refer your readers to the original paper for the full context. . . . "when our views are sufficiently extended, to enable us to reason with precision concerning the proportions of elementary atoms, we shall find the arithmetical relation alone will not be sufficient to explain their mutual action, and that we shall be obliged to acquire a geometrical conception of their relative arrangement in all the three dimensions of solid extension. . . . when the number of one set of particles (combined with one particle), exceeds in the proportion of four to one, then, on the contrary, a stable equilibrium may again take place, if the four particles are situated at the angles of the four equilateral triangles composing a regular tetrahedron. . . . It is perhaps too much to hope, that the geometrical arrangement of primary particles will ever be perfectly known." Thus Wollaston's conception of the combination of four particles with another is exactly the same as our modern idea of the arrangement of four monovalent atoms (or groups) in combination with a carbon atom. The same idea is also developed somewhat later by Ampère in his "Letter to Berthollet" (*Annales de Chimie*, 90, p. 43–86, 1814), in which he considers the molecules as forming various geometrical figures dependent on the number of atoms contained therein.

JOHN CANNELL CAIN.

The Owens College, Manchester, December 14.

THE MANŒUVRING POWERS OF STEAMSHIPS AND THEIR PRACTICAL APPLICATIONS.

IN a recent number of the *United Service Magazine*, I wrote an article tracing briefly the history of manœuvring powers of steamships as ascertained and applied, or as assumed and applied, or as omitted in application, to the purposes of war and navigation. It was chiefly addressed to the Navy as my apology for certain published views on the causes of the loss of the *Victoria*, but it is suggested that a *résumé* with diagrams would interest the readers of NATURE.

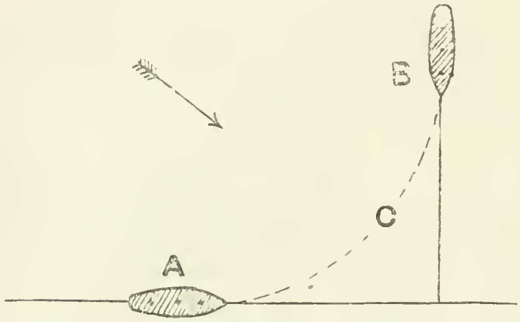

FIG. 1.

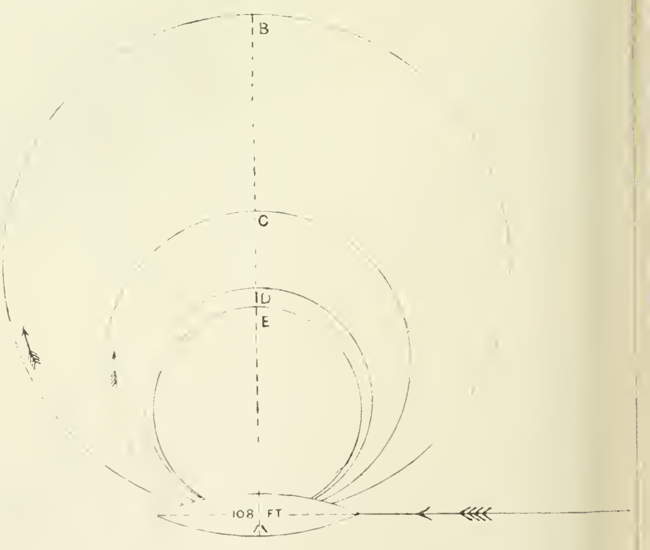
Quite in the early days of steamers it was noticed that when they turned under the influence of their helms, they took a wider and more regular sweep than seamen were accustomed to notice in sailing-ships. There was a limit to their powers; for when a steamer had put her helm "hard over," she had done all she could to turn "sharp," and if the turn was not sharp enough to avoid collision, for instance, it inevitably took place unless she could check her impetus in time by reversing her engines.

When steamers began to multiply—I speak of a date before 1854—collisions with them began to multiply also, and it was necessary to devise "rules of the road" for their prevention, such as sailing vessels had for generations possessed amongst themselves. Admiral Beechey, to whom the matter was confided, could not escape from his knowledge of the sweep that steamers made in turning, but it did not occur to him to make any investigations into its nature. He assumed it. Having done so, it did not occur to him that the application of his assumption could only be made by diagram to scale. He therefore based a proposed law on the assumption that the first 90° of a ship's path was a circular arc, but he did not specify what its radius might be in terms of the ship's length. I reproduce in Fig. 1 the fundamental diagram of the great "law of port helm" which was set out in Clause 296 of the Merchant Shipping Act, 1854, and was finally condemned by Parliament in August, 1860. The fact was that no steamer ever did, or could, turn on the path represented, and that the law could not have been drawn had the Admiral been aware of the real path, and had he applied it by means of diagrams drawn to scale.

When the single screw began to supersede the paddle, the characteristics of the turn remained, but constructive difficulties increased the sweep in warships. The late Admiral Sir Cooper Key, being in charge of the Steam Reserve at Devonport, carried out investigations—very incomplete in those days—which culminated, in 1863, in a series of experiments with a gunboat, directed to ascertain the relations between helm-angle, area of rudder, and the length and duration in time, of the path described in turning completely round. It was still assumed that the path was circular from first to last, and the results as to helm-angle are shown in Fig. 2. The "diameter" of an assumed "turning circle" was the comparative space-measurement employed. The result of the experiments was the introduction of the "balanced rudder" into the Navy.

Our first ironclad, the *Warrior*, had been more than a year at sea when these experiments were made. She was 380 feet long, much longer than any other man-of-war, except her sister, the *Black Prince*, and the time she took to turn round, as well as the space she evidently covered, were tremendous. Still assuming that every part of her path in turning was circular, means were devised to measure its "diameter," which was found to be six times her length, or 760 yards; while, at 12 knots, it took her 7m. 46s. to turn completely round. Everyone was much impressed, but the smallness of the helm-angle—22°, due to want of power to move the rudder over—was much less noticed than the length of the ship; and the fact bore remarkable fruit.

Great changes of thought on the subject of manœuvring occurred both at home and abroad. Everywhere the idea of the circular arc was accepted; no means had been invented for discovering the form of the path, and it was not sufficiently plain that only the first 180° of the turn was of any importance, and that knowledge of the nature of the path for the first 90° was the most important of all. Abroad, the idea of the circular arc was made the substructure of vast and embracing theories. Admiral Boutakov, of the Russian Navy, based a complete system of tactics on the diagram reproduced in Fig. 3, which he called "tangential arcs." It may be seen that the path from S to S′ does really embrace the whole question of helm-manœuvres. But no ship beginning to turn at N, and turning back again, could ever, by any possibility, reach W, or S′. The assumptions were entirely apart from the facts. At home, we contented ourselves with ordering that the time any warship took to turn half-round, and



A B = 534 feet 18° of helm. | A D = 238 feet 40° of helm.
A C = 318 feet 30° of helm. | A E = 216 feet 45° of helm.

NOTE.—The ship is drawn on twice the scale of the rest of the diagram.

FIG. 2.—Scale, ½ inch = 100 feet.

completely round, at named speeds, should be recorded, and that the "diameter" of her "turning circle," measured in any way that seemed suitable, should at the same time be ascertained. No advance in the matter could be arrived at by any single experiment of this kind, but I found in later years that a great fund of knowledge

lay buried, which could be dug up when numbers of the experiments were compared.

Meantime the condemnation of Admiral Beechey's law by Parliament had put those concerned on devising a substitute. Discussions over the subject went on from August, 1860, to January, 1862, but there is nowhere any sign that the manœuvring powers of the ships to be dealt with ever came into view at all. A single diagram survives, which is reproduced in Fig. 4. It is obviously not to scale, but was intended to show that a movement proposed to be prescribed for one of the ships would be a

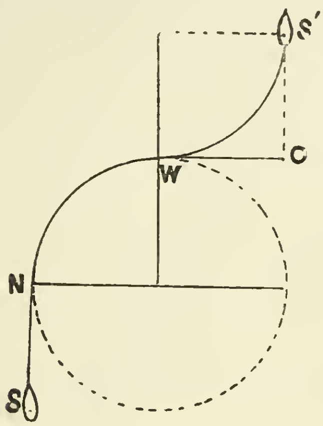


FIG. 3.

dangerous one. It was not noticed that if scale were applied to the diagram, it would show that no possible movement on the part of either ship could avoid the inevitable collision.

The Rules of the Road of 1862 have been continually modified since; and by some appeal to experiment as applied to diagram, the British delegates at the Washington Conference in 1889 were able to carry material amendments. But the fallacy of the original basis has been perhaps most forcibly brought out by Mr. John

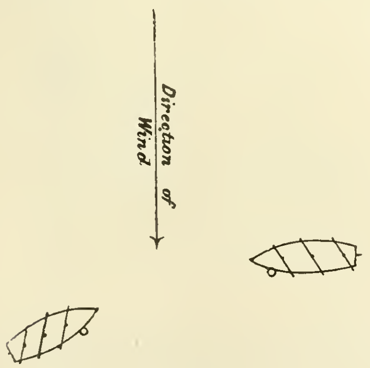

FIG. 4.

Glover before the Statistical Society in 1892. He showed that while in the decade 1880–90, all other wrecks about the coast of England have been reduced from 705 to 353 annually, the wrecks by collision have increased from 69 to 72 annually.

The Rules of the Road—not yet superseded by those of the Washington Conference—were once very carefully attacked by means of experiment and diagram to scale. The answer, made by the highest authority at the time, was based on the diagram reproduced in Fig. 5. The point was, what action No. 1, when steering at different angles across No. 2's path, ought to take to avoid her. The diagram is again clearly not to scale; but if scale be applied, it is seen that No. 1 is always so placed that no steps taken by her could possibly avoid collision.

In 1865 I had the honour to be entrusted by the Admiralty with the task of designing a system of manœuvring iron-clad steam fleets to supersede that under which Nelson had fought his battles, and which still remained intact. I was enabled, by the kindness of the Admiral commanding the Channel Fleet, to carry out a series of experiments, incomplete no doubt, but sufficient for my immediate purpose. The reduction of these experiments to scale diagrams became the basis of a system of manœuvring which has scarcely been modified, though it has been added to, down to the present day. The flaw in it undoubtedly was the enforced assumption of the circular arc, by the want of better methods of measurement, and the fact that Boutakov's diagram represented general belief.

The failure to duly connect helm-angle with the turning powers of the *Warrior* now began to bear its fruit

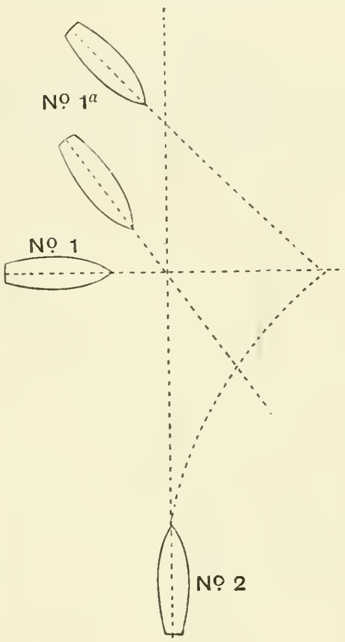

FIG. 5.

in a new direction. The present Sir Edward Reed, K.C.B., became Chief Constructor of the Navy in 1863. He was greatly impressed, as everyone then was, with the necessity of good manœuvring powers in men-of-war. He connected bad manœuvring powers, as everyone else then did, with length, and he was not impressed more than anyone else was, with the desirability of systematic experiment to ascertain what manœuvring powers really were, and what share different elements had in influencing them. He proceeded, with universal commendation, to reconstruct the Navy on the thesis that a short ship was necessarily a better manœuvrer than a long ship. His *Bellerophon*, only 300 feet long, was laid down in 1864, and his *Hercules*—still regarded by the whole Navy with affection—only 325 feet long, was laid down in 1866. Sir Edward was justly proud of the manœuvring powers of the *Bellerophon*, whose "diameter" was only 401 yards, as compared with the *Warrior's* 760. It was not sufficiently noted that the smaller space was due in greater proportion to the increase of helm-angle, by means of Captain Key's

balanced rudder, from 22° in the *Warrior* to 37° in the *Bellerophon*, than from the decrease in length from 380 to 300 feet. But it was really for want of experiment and diagram reduced to scale, that the error was committed of exaggerating the element of length. As a fact

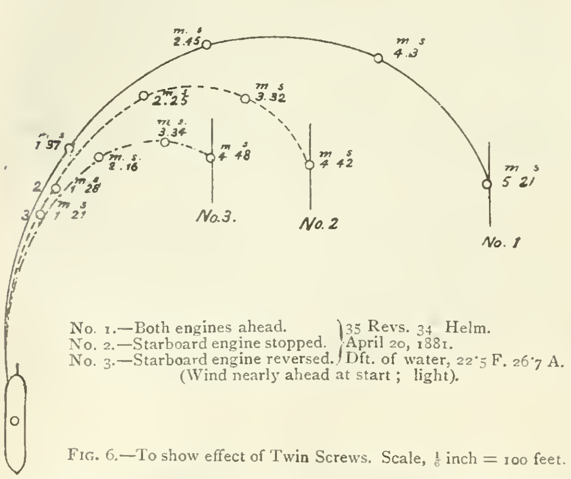

FIG. 6.—To show effect of Twin Screws. Scale, $\frac{1}{8}$ inch = 100 feet.

it is but one element out of many. The *Edinburgh*, for instance, which is 325 feet long, requires a "diameter" 93 yards longer than the *Minotaur*, which is 400 feet long.

beginning to be applied to the rudders, so that any helm-angle provided for, could be obtained at any speed. These changes in the elements of manœuvring powers demanded especial study; and, most of all, some more complete and accurate method of measurement. Anticipating, I here show, in Fig. 6, what these developments came to in the case of H.M.S. *Thunderer*, and how little modification the twin-screw can make in the early part of the turn.

The invention of a satisfactory method of measurement is due to Mr. Philip Watts, late of the Admiralty, who, in the year 1877, applied it to the *Thunderer* for purposes that had nothing to do with manœuvring. But the experiments showed how very far from circular the path really was, and how misleading the idea of a circular path had been. Collisions, unaccountable before, were now easily accounted for, and a terrible opportunity of bringing the new light to bear was offered when, in 1878, the *Bywell Castle* ran into and sank the *Princess Alice*, destroying 600 lives. The accident was wholly a question of manœuvring. Starting, as it was possible to start, with the assumption that the *Princess Alice* was legally wrong in turning to the left when approaching the *Bywell Castle*, disclosing her movement by exhibiting first her red and then her green light in front of the latter ship, the question remained as to what was safe for the *Bywell Castle* to do? She did turn to the right and sink her neighbour. Ought seamen to be instructed that the movement was a right or a wrong one as an answer to the signal received? The diagram which is reproduced in Fig. 7, was carefully prepared by putting all the facts into line with the best experiments, but it was found im-

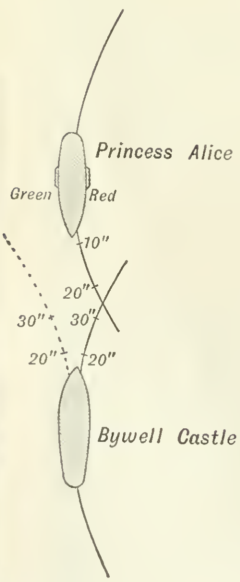

FIG. 7.—Scale, $\frac{1}{4}$ inch = 100 feet.

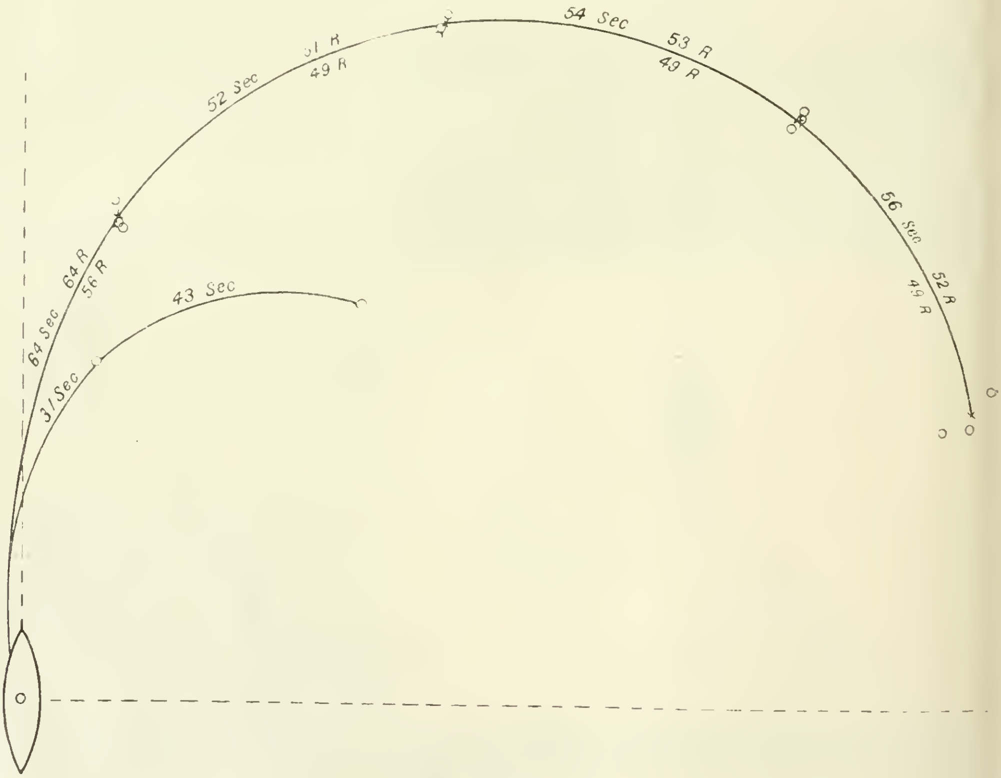

FIG. 8.—Scale, $\frac{1}{4}$ inch = 100 feet.

The twin-screw began to make its appearance in the early days of Sir E. Reed's control of our shipbuilding, and he pushed it forward vigorously. Several twin-screw battleships were launched, and others laid down before he left office in 1870. At the same time steam power was

possible to bring ideas of the manœuvring powers of the ships, and the causes of the accident, together into the discussion. The form of the accident was common, and it remains common; but no teaching yet exists which might help seamen to avoid it.

It was somewhat remarkable that in this same year in the Navy, just, it might be said, when the means of fully applying the experimental method to fleet manœuvring became available, the tide set strongly against experiment. The recommendations for experiment were curtailed, and special promptings and means for carrying out experiments, which had been usefully employed for four years, were withdrawn. The feeling grew that what had been done in 1865 was sufficient for all time; and those who were responsible for errors and shortcomings in 1865, because of the defective means for experiment, found themselves met by the stubborn character of their own mistakes when they desired to amend them. The Navy became too satisfied with the work of 1865, and felt in everything else disposed to trust to the chances and judgment of the moment when manœuvring the ships in a fleet. What was lost by failure to pursue the experimental method was not seen, and when I state clearly that if the experimental method could have been persevered in and developed, we should not have lost the *Victoria* and Sir George Tryon, my views are scarcely apprehended by the Navy. I cannot enter upon this matter here, though I shall presently make a remark on it which will then be understood. I must conclude my paper by setting forth some of the results which have been obtained by the experimental method.

In the first place it seems made out that every improvement in the method of measuring manœuvring powers has shown less apparent variation in the movement of ships under given conditions; and when, with any given method, the observers grow skilled, the apparent variations of movement become less. The accuracy of movement of all ships at speed when turning is remarkable. The curve traced in Fig. 8 is the mean of three turns of 180° to the right, made by the *Edinburgh*, at an original speed of twelve knots, and with a helm-angle of 34°, reached, by means of steam steering gear, in 11 seconds. The small circles represent the successive positions fixed by observation when the turn had reached 45°, 90°, 135°, and 180°. The figures on each side of the trace represent the total revolutions of each screw, and the seconds marked denote the time occupied in passing over each "octant." The accuracy of the turn is apparent to the eye, and while the space measurements in no case vary more than 60 feet from the mean, the time measurements do not vary more than five seconds from the mean, and that is out of a total of 220 seconds.

To the figure is added a trace of the *Edinburgh's* powers of reducing the size of her arc and her speed over it, by reversing both engines full speed, as simultaneously as possible with the movement of the helm.

Fig. 9 traces a path which is the mean of three turns made by H.M.S. *Dreadnought* at 10·9 knots speed with 32° of helm, where the apparent variations in the path seem to be greater. But the space variations here are never more than 74 feet from the mean, while the times

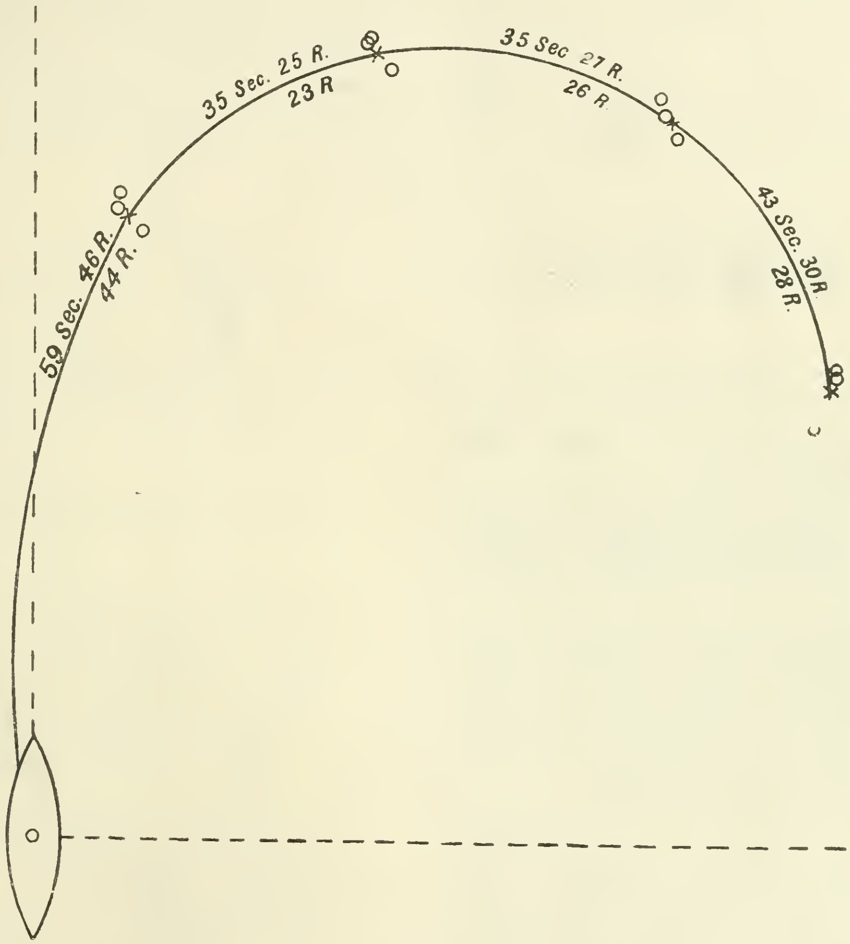

FIG. 9.—Scale, $\frac{1}{3}$ inch = 100 feet.

do not vary more than eight seconds from the mean out of a total of 176 seconds. This remarkable precision has been always found. It was equally present in a steam

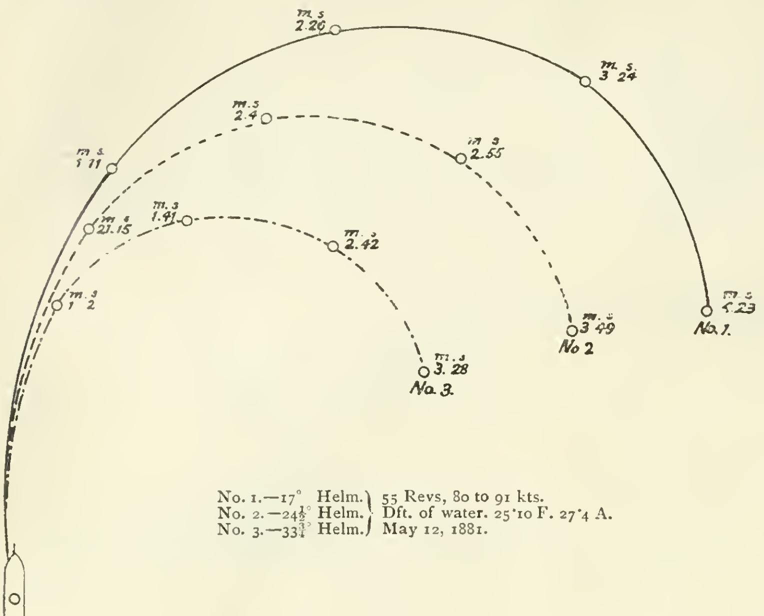

FIG. 10.—To show effect of Helm-angle. Scale, $\frac{1}{8}$ inch = 100 feet.

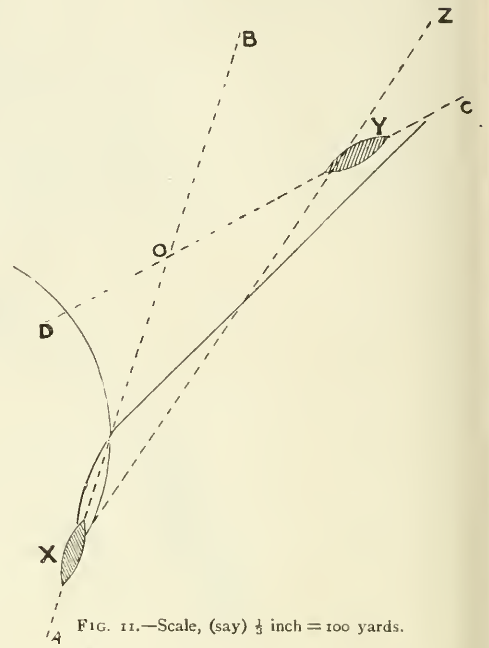

FIG. 11.—Scale, (say) $\frac{1}{3}$ inch = 100 yards.

pinnace, and the one experiment made with a very light ship in a high wind failed to disclose any difference due to differing directions of the wind.[1]

The traces of the *Edinburgh* and *Dreadnought* are brought together in order to exhibit the wide differences that exist in the form of the path described by different ships in turning. They show how imperative it is that in fleets, at any rate, these differences of form should be recognised.

But the peculiarity of the form of the path remains nearly the same at all helm-angles, and this makes the necessary equalising of the paths for the purposes of fleet manœuvring easier. It shows, too, the fallacy of the 1865 idea—still preserved—that there can be a single "evolutionary helm-angle" suitable to equalise a large or a small turn. The facts are illustrated by Fig. 10, which shows the effect of varied helm on H.M.S. *Thunderer*.

I have now only to point out how experiment bears on the question of collision between ordinary ships at sea. The ordinary form of approach before collision is given in Fig. 11. The law enjoins that Y should keep steadily to her path, and that X should "keep out of her way." In order to do so, she has been for something like thirty years told that she must decide for herself whether to turn to the left or to the right. Needless to say that as she cannot hope to turn "sharper" than the path marked for her, she generally produces collision by turning to the left, but she is never explicitly condemned for that act.

Ships often only discover one another when so close that it cannot be certain which has the power of avoiding collision. Fig. 12 supposes two *Edinburghs* meeting under such conditions, where it is seen that safety can alone lie in knowledge of the general manœuvring powers of ships and their application to the particular case. Admiral Beechey's law would have caused both these ships turn to the right, and would have made collision inevitable. The existing law—if it were acted on—would compel Y to keep her course, in which case also collision would be inevitable. The natural law, based on experiment, would make each ship turn towards the other, X turning to the right, and Y turning to the left; in which case it would not be possible for the ships to touch

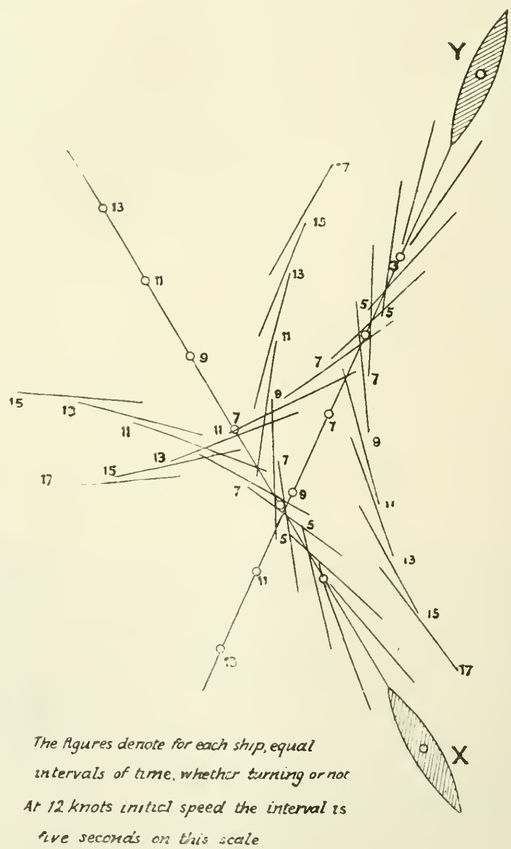

FIG. 12.—Scale, ·288 inches = 100 yards.

[1] I have by me many scores of experiments made with fifteen or sixteen ships and vessels of all sizes and classes.

at all. The rule would evidently apply safely in every such case, unless the ships had nearly equal manœuvring powers, and were then so placed that their turning arcs coincided; two concomitant conditions almost impossible to exist. Needless to say that the results of actual collisions exactly follow the diagram.

It now remains to express my general belief as to the *Victoria*. The paths in turning given of the *Edinburgh* and *Dreadnought* are those of two of the ships which were present on the occasion of her loss. Whether or not they had these traces on board I do not know. There is no mention of such things in the Minutes of the Court Martial, and the questions and answers never go beyond the work of 1865–74. But it is to me inconceivable that the mistake could have been made had such traces been familiar in every ship, and had the late Sir George Tryon been supplied with those of all his ships as a matter of course.

I think that, while blame for this accident has been authoritatively and unauthoritatively strongly thrown on individuals, it is impossible for anyone realising what I have written, to blame any one individual.

P. H. Colomb.

THE TUNICATE.

Far down in the depths of the ocean
  The Tunicate's active and gay;
It hasn't the ghost of a notion
  How cellular tissues decay.

With a notochord all down its central part,
  It is surely a wee morsel vain;
For it knows it possesses a ventral heart,
  Not to speak of a dorsal brain.

Then down in the depths of the ocean
  The Tunicate's lightsome and free;
It hasn't the ghost of a notion
  How degenerate old age can be.

For it must be a pleasing sensation
  That, if other resources all fail,
You can never come quite to starvation
  If you've been endowed with a tail.

Then down in the depths of the ocean
  The Tunicate's careless and glad;
It hasn't the ghost of a notion
  Its instincts all tend to the bad.

Till, wearied by youthful diversion,
  It thinks it will rest on a stone.
It becomes disinclined for exertion.
  —Ah! Tunicate, you are undone!

Now, down in the depths of the ocean
  That Tunicate's losing his tail:
As though he had swallowed a potion,
  His mental resources all fail.

His brain and his nerves they degenerate,
  His notochord meets a like fate;
You hardly can class him, at any rate
  He's no longer a true vertebrate.

And down in the depths of the ocean
  He gets him a cellulose frock;
And all just because of that notion
  Of taking a rest on a rock.

And there is a moral deduction,
  Which I'd like you to cogitate often:
Don't we all know of stones where, by suction,
  We stick, till our intellects soften?

R. M.

NOTES.

The Croonian lecture of the Royal Society for 1894 is to be delivered by S. Ramón y Cajal, Professor of Histology and Pathological Anatomy in the University of Madrid. The subject will be "The Minute Structure of the Nervous System," and the date, March 1.

On February 16 next, Prof. E. Haeckel celebrates his sixtieth birthday, and in honour of the event it is proposed to place his marble bust in the Zoological Institute of Jena. Friends and admirers of Haeckel who desire to support this object, should send their subscriptions to Prof. Richard Semon, Jena.

Miss Klumpke, the well-known lady assistant at the Paris Observatory, took the degree of Doctor of Mathematical Science at the Sorbonne, on December 14. The subject of her thesis was Saturn's rings.

Profs. Barnard and Asaph Hall have been awarded the Arago Prize for Astronomy by the Paris Academy of Sciences.

Prof. C. F. Mabery has received a grant of 300 dollars from the American Academy of Arts and Sciences, to enable him to carry on his investigations of the American sulphur petroleums.

The death is announced of Dr. J. Boehm, Professor of Botany in Vienna University, of Dr. D. A. Brauns, Extraordinary Professor of Geology in Halle University, and of Dr. P. A. Spiro, Professor of Physiology in the University of Odessa.

It appears from the will of the late Sir Andrew Clarke that he has bequeathed the sum of £500 to the London Hospital Medical College, for the foundation of a scholarship.

At a special general meeting of the Royal Institution of Great Britain, held on Friday last, the following resolution was unanimously adopted:—"That the members of the Royal Institution of Great Britain, in special general meeting assembled, hereby record their deep regret at the death of Dr. John Tyndall, D.C.L., LL.D., F.R.S., who was for forty years connected with the institution as lecturer, professor, and honorary professor of natural philosophy, and who by his brilliant abilities and laborious researches nobly promoted the objects of the institution and conspicuously enhanced its reputation, while at the same time he extended scientific truth, and rendered many new additions to natural knowledge practically available for the service of mankind; and that the members of the Royal Institution further desire to convey to Mrs. Tyndall an expression of their sincere sympathy and condolence with her in the bereavement she has sustained in the loss of her gifted and distinguished husband."

We learn from the *Victorian Naturalist* that Baron von Mueller has withdrawn from the directorship of the International Academy for Botanic Geography of Le Mans.

After remaining dormant throughout historic time the volcano El Calbuco in the Andes (Lat. 41° 21′ S. Long. 72° 38′ W.) has renewed its activity. Mr. A. E. Nogues described the eruption in a communication to the Paris Academy, on December 11. Some months ago, columns of vapour began to issue from the crater, their escape being accompanied by the usual subterranean noises, seismic movements, and electrical phenomena. This stage was followed by the ejection of scoriæ and rock fragments in such large quantities that the surrounding woods were burnt up, and the ground raised to a comparatively high temperature. At the present time the volcano is in full play. Lava has issued from the sides of the cone and flowed down to the base, forming streams of molten rock which have barred the way of torrents and changed the directions of rivers. This phase of the eruption, however, marks a decline of activity, and will in all probability be followed by the quiet emission of gaseous products.

BY the generosity of M. G. Solvay, two important institutes have been established at Brussels, namely, a University Institute of Physiology, and an institute specially designed for carrying on electro-biological researches. In May last M. Solvay presented the town with a sum of two hundred thousand francs for the erection and equipment of the University building, stipulating only that the University should provide courses in physiological chemistry, and medical physics relating to the connection between physiology and electricity. This condition was laid down with the object of improving the instruction at the University, and developing the spirit of investigation in the minds of students, thus giving them the ability to carry on physiological researches independently in a special laboratory. For students thus trained, and desiring to apply their knowledge to research of a special kind, the Solvay Institute has been established. At the inauguration of this institute, on December 14, M. Solvay delivered an address on the rôle of electricity in the phenomena of life. He remarked that his conviction was that the phenomena of life could probably be explained by the action of physical forces, and that, among these forces, electricity played an important part. It was to obtain evidence on this point, by the observation and study of facts, that M. Solvay was led to found the institute that bears his name.

AN appeal has been made for funds to establish a small station at Millport for the study of the marine zoology and botany of the Firth of Clyde and West of Scotland generally. It is intended to establish in connection with the station a representative collection of local marine fauna and flora, and, should the funds permit, to construct tanks for the study of living animals and plants. A station, on a limited scale—centred in a small vessel called the *Ark*—has existed at Millport for some years, and has been found exceedingly useful. During 1891 and 1892, the Royal Society of London gave a grant of £100 for the investigation of the algæ of the Clyde sea area. This work was carried on chiefly in the *Ark*; the result being that about eighty species new to the district were found, and of these between twenty and thirty were new to Britain, and about six new to science. The advantages which a permanent station would offer to students of natural history are sufficiently obvious. As the scheme has the cordial approval of many of the Professors at Glasgow University, and also the support of local naturalists, there should be little difficulty in obtaining the contributions required to realise it.

WE learn from the Allahabad *Pioneer* that subscription lists will be opened immediately for the Pasteur Institute scheme. The Amritsar municipality have sanctioned a donation of 1000 rupees and an annual subscription of 500 rupees. The Gurdaspur municipality had previously promised a donation and an annual grant, and among other donations promised are 1000 rupees from Khan Bahadur Barjorjee D. Patel of Quetta. The Government of India have promised to give the services of a qualified medical officer to superintend the institution, which is equivalent to an annual donation of at least 12,000 rupees. Altogether the committee will commence their work under most favourable auspices.

MR. E. A. MINCHIN, whose election to a Fellowship at Merton College, Oxford, we noted last week, was placed in the first class in the Honour School of Natural Science (Animal Morphology) in 1890, and has since been a Demonstrator in the Linacre Department of Comparative Anatomy. It is understood that the examiners sent in a special report to Merton College, to the effect that all of the eleven candidates for the Fellowship acquitted themselves with distinction, and were, in the opinion of the examiners, fully up to the standard required.

THE following appointments have recently been made in America:—Mr. W. S. Aldrich, Professor of Mechanical Engineering, West Virginia University; Mr. F. F. Almy, Professor of Physics, Iowa College; Dr. Charles E. Coates, Professor of Chemistry, Louisiana State University; Dr. A. J. Hopkins, Professor of Chemistry, Westminster College, Pa.; Dr. H. B. Loomis, Assistant Professor of Physics, Northwestern University; Dr. M. M. Metcalf, Professor of Biology, Woman's College of Baltimore; Mr. A. M. Muckenfuss, Professor of Chemistry, Millsaps College, Miss.; Mr. S. L. Powell, Professor of Natural Sciences, Newberry College, S.C.; Dr. H. L. Russell, Assistant Professor of Bacteriology, University of Wisconsin; Dr. J. N. Swan, Professor of Chemistry, Monmouth College, Illinois.

IN a recent *Bulletin* the State Board of Health of Michigan makes the assertion that the statistics of sickness indicate a connection between atmospheric ozone and influenza. Speaking generally, influenza increases with the proportion of ozone in the atmosphere. On the other hand, remittent fever decreases as the proportion of ozone increases.

THE following science lectures will be given at the Royal Victoria Hall during January:—Prof. Smithells on "Flame"; Mr. R. W. Frazer on "Life in South India"; Mr. F. W. Rudler on "Diamonds"; and Dr. Waghorn on "Our Eyes, their merits and failings."

WRITING upon "South American Meteorology," in the *American Meteorological Journal* for December, Prof. W. H. Pickering remarks that the Harvard College Observatory has four meteorological stations in Peru, all within one hundred miles of one another. The first is at Mollendo, on the sea coast, with an altitude of 100 feet: the second is at La Joya, in the desert—altitude 4140 feet; the third is the observatory in the Arequipa oasis—altitude 8060 feet; and the fourth is at the Ravine Camp upon Mount Chachani—altitude 16,600 feet. A fifth has recently been established, by Prof. S. I. Bailey, upon the summit of the Misti, at an altitude of 19,200 feet. The observations made at these observatories will doubtless lead to a much more accurate knowledge of the meteorology of Southern Peru than we at present possess.

AT the meeting of the Royal Society of New South Wales, on November 1, Mr. H. C. Russell described a new form of rainfall map. Instead of having different tints to indicate different amounts of precipitation, Mr. Russell divides the area over which the observations extend into square degrees, and by means of large figures printed on each square, shows to the nearest quarter of an inch the mean rainfall for that spot. Other smaller figures are used to show the number of years the observations have been made, and the number of stations used to find the mean. The map thus gives a large amount of information about the average rainfall of a country, and, at the same time, it shows in a conspicuous manner lines of equal rainfall and outlines of large areas of heavier rainfall, like the shaded maps; giving, in addition, what the shaded map cannot exhibit, viz. the variations in the rainfall of these areas of heavier rain. A map of New South Wales was prepared on this principle by Mr. Russell, specially to meet the wants of the agriculturist; but after it had been completed, it was found to serve the requirements of the meteorologist better than any map constructed on the shaded plan.

IN *Hansa* of the 9th instant, Captain C. H. Seemann discusses the meteorological conditions which accompanied or preceded the slight outbreak of cholera at Hamburg this year, and the serious epidemic of 1892. A comparison of the curves of the temperature of the air and the water of the Elbe for the corresponding period of each year shows scarcely any difference,

while the level of the river was lower near Hamburg this year. It appears from the facts brought forward, that meteorolgical conditions were in no way connected with the outbreak or spread of the disease, and that the cause must be attributed entirely to the accidental contamination of the water of the Elbe.

AN abstract on the "Occurrence of Amber in Russia," by Fr. Th. Köppen, is published in *Petermann's Mitteilungen*, November 1893, pp. 249-253. The original paper by the same author appeared in a Russian publication. Amber is found on the Baltic shores, the south coast of the Gulf of Riga, and in turf-moors or ancient gulfs of Kurland, embedded below thin beds of turf or sea-sand. Farther north, it occurs on the shores of the Oesel Island, and even in South Finland. The Polish localities along the river Narew are supposed to have been those referred to by Pliny. The most extensive occurrence is in the western provinces of Russia, and in different places on the banks of the Dneiper. From these facts, the "amber-formation" may be said to occur in Western Russia, from the Baltic to the Black Sea. A recent paper, written by N. Sokolow, shows that the lower tertiary deposits of Southern Russia extend also throughout this area. Sporadic appearances of amber occur in the southern parts of Bessarabia in brown-coal strata; they are possibly associated with the amber found in Roumania. Other Russian localities are the Arctic shores of Russia and Siberia, and on the Sea of Okhotsk. A sketch-map accompanies the text, showing the distribution of lower tertiary deposits according to Sokolow, and the most important occurrences of amber in Russia.

LAST week's number of *Die Natur* concludes a series of eleven articles written by A. and S. Ortleb. The title of the series is "Introduction to specimen-collecting, geological and palæontological." The early chapters run rapidly through the physical and geological history of the development of our earth, and point out the significance of the fossils found in sedimentary beds. A short, systematic description follows of the chief groups in the plant and animal kingdoms. A few of the more interesting genera are mentioned, illustrations are given along with the text, and care is taken to bring out the particular epochs and localities to which the fossil representatives belong. This admirable contribution to popular scientific literature will supply a want widely felt among amateur collectors in Germany.

MR. M. CAREY LEA, who recently described a method of transforming mechanical work into chemical action in the *American Journal of Science*, has been continuing these interesting researches, and gives a description of some further remarkable results in the current number of the same journal. Instead of an enormous simple pressure, he tried shearing stress, and obtained more striking and apparent reactions than by the former method. In one series of experiments he placed a small quantity, a few decigrams, of a metallic salt in a mortar, spread it into a thin uniform sheet over the bottom, and rotated the pestle with the utmost force that could be exerted. Two of three decigrams of chloroaurate of sodium left 1·8 milligram or metallic gold. Under the action of the pestle the yellow colour of the salt gradually deepened to an olive shade. When water was poured on, the undecomposed salt dissolved, leaving the gold as a delicate purple powder. Half an hour's trituration of half a gram of the salt resulted in the reduction of 9·2 mgrms. of gold. This reduction represented the conversion of about 500 gram-meters work into chemical energy. Since the reaction is endothermic, there is no doubt that the energy was derived from the mechanical power. That the reaction was not produced by heat was proved by carrying on the operation intermittently, when the reaction took place in the same way, and also by the partial reduction of corrosive sublimate to calomel by a similar operation. By heat, corrosive sublimate sublimes unaltered. The same conclusion can be drawn from other reactions. Salts of mercury, platinum, and silver gave results analogous to those in the case of gold. In another series of experiments Mr. Carey Lea imbued pure strong paper with a solution of the substance, dried it thoroughly, and laid it upon a piece of plate glass. Characters were then marked on it with the rounded end of a glass rod, using as much pressure as possible without tearing the paper. Marks were thus immediately obtained in the case of potassium ferricyanide, gold and platinum chlorides, mercuric oxide, and many silver salts. The author accounts for the more immediate action of shearing stress in effecting chemical changes by the increased vibration and consequent shattering of the molecules, the action being analogous to that brought about when a bow is drawn over a stretched cord.

THE third number of the *Physical Review* contains a paper, by Alexander Macfarlane and G. W. Pierce, on the electric strength of solid, liquid, and gaseous dielectrics. In the course of a previous research Dr. Macfarlane had found that the "electrical gradient" necessary to force a spark through a thin stratum of dielectric diminishes as the thickness increases, when air or other gas is the dielectric, but remains constant when turpentine or other insulating liquid is the dielectric. Mr. Steinmetz has shown that solid dielectrics, such as paraffined paper, behave in the same way as the liquid dielectrics. In order to obtain more trustworthy observations on these points, the authors have compared the electrical gradient necessary to break down different solid and liquid dielectrics with that required in the case of air. For this purpose they employed two discharging tables, each table supporting two parallel discs about 4 inches in diameter, the connecting rods being joined to the poles of a Holtz electrical machine, so as to form two alternative paths for the discharge. One of the tables, that used for the air gap, was provided with a micrometer by which the distance between the plates could be measured. The sheets of dielectric were placed between the other pair of discs, and the air gap enlarged till a spark passed through the solid dielectric. The difference of potential required was calculated from the length of the air gap, using the results published by Macfarlane and Steinmetz. The equivalent thickness of air is not proportional to the thickness of the solid or liquid, but increases more rapidly as the stratum increases in thickness; the difference of potential, however, required to break down a solid or liquid dielectric is proportional to the thickness. Thus it appears that while thin strata of solid or liquid dielectrics are equally strong whatever the thickness, thin strata of gaseous dielectrics grow weaker as the thickness increases. The authors consider that this difference is not due to a surface phenomenon, but to the greater rarity of the gas which allows discharge by convection to be more readily set up. They find that for liquids, when the thickness is considerable, convection currents are sometimes started, and that in this case the discharge takes place at a lower difference of potential.

Wiedemann's Annalen for December contains a description of a modified form of Thomson quadrant electrometer, which has been employed by Herr F. Himstedt. The chief characteristics are the employment of the form of needle which Lord Kelvin uses in his multicellular voltmeter, suspended by a quartz fibre. The lower end of the row of needles carries an insulating stem, to which are fixed two small magnets. These magnets are placed with their axes vertical, so that the earth's magnetism has no tendency to cause rotation of the needles, and are surrounded by a thick copper shield, the induced currents in which damp the oscillations of the needle. The fibre by which the needle is suspended is covered with a thin coat of deposited silver, so that it conducts, and thus allows the needle to be

charged. With a period of 22 seconds, and when the needle is charged by means of 80 small accumulators, one Clark cell gives o f 800 scale divisions on a scale 250 c.m. from the instrument.

Just now Saxony, of which Chemnitz is the most important manufacturing centre, is interested in the comparisons being made in Switzerland between steam-power plants and electricity gained by utilising water. In connection with this subject the United States Consul at Chemnitz has recently made the following remarks (*Board of Trade Journal*):—"It used to be urged that Switzerland's water supply, if properly utilised for obtaining electricity, would reduce very considerably her cost of production. Not only has she many streams, but they fall from such heights that even rivers of small volume have great power. . . . Every effort that science could suggest, ingenuity devise, or mechanics arrange, was made in different cantons of the little Republic to gather electricity by, and transmit it from, her rivers and streams. The latest reports show that if Switzerland, or any country with streams and climate like hers, is to win her way into the world's markets and take a place in the front ranks, it must be by some better method than the use of electricity gained and transmitted from rivers and waterfalls." Electricians will doubtless have something to say on this matter.

One of the factors in the so-called self-purification of river-water is regarded by some authorities to consist in the destruction and oxidation by bacteria of some at least of the organic material present. Prof. Pettenkofer, who has been investigating the condition of the river Isar, in the vicinity of Munich, is of opinion that the green living algæ found in this water also play no unimportant part as purifying agents. Prof. Schenck (*Centralblatt f. Allgem. Gesundheitspflege*, 1893), who has been making a special study, from this point of view, of the Rhine in the neighbourhood of Cologne, mentions that, to his surprise, he found comparatively few algæ where most impurities were present, the former being apparently crowded out by the large masses of bacteria. On the other hand, Prof. Percy Frankland has recently stated that, contrary to what might have been anticipated, he found a comparatively small number of bacteria present in the water of a loch, which was so turbid that it was practically opaque when viewed in a glass, by reason of the immense number of algæ present. Dr. Schenck's investigations were carried out to ascertain if the city of Cologne could with safety discharge its sewage untreated direct into the river, relying upon the processes of subsequent self-purification for the water to regain its normal condition. The mass of algæ found was remarkably small, being chiefly confined to the shallows along the banks, or to those spots where protection was afforded from the rush of the stream; the varieties, moreover, present were found to vary very considerably at different seasons of the year. But according to Prof. Schenck, the condition of the river banks in the immediate vicinity of the site selected for the entry of the Cologne sewage is very suitable for the aggregation of masses of bacteria, and he maintains that in conjunction with other factors of purification, such as mass of water and rate of flow, &c., a rapid and thorough purification of the water may be expected. Whatever the general opinion may be of the wisdom of Prof. Schenck's advice, his investigations show that the alleged action of green algæ as important water purifiers cannot be accepted without reservation, but that in the case of each river or stream the nature and growth of these plants must be studied.

The first part has been sent to us of a work entitled *Sporozoen als Krankheitserreger* (Berlin: Friedländer and Sohn, 1893), by Dr. Alexis Korotneff, Professor at the Kiew University, and Director of the Zoological Laboratory in Villafranca. This "Heft" is devoted to "Untersuchungen über den Parasitismus des Carcinoms," and is illustrated by four beautifully coloured plates showing the structure of the tissue in cancerous tumours, and the presence of parasites in various stages of development. The large amount of work which has been published during the last three years since Nils Sjöbring's paper on the parasitic nature of this disease appeared, renders a critical summary, such as Dr. Korotneff has written, of particular interest. The author admits, however, that personally the number of cancerous cases which he has examined is insignificant, but adds that the greater part of the drawings which have appeared in the works of Sudakewitsch, Sawtschenko, Kossinsky, Ruffer, and others on this subject, which are based upon observations made upon hundreds of cases, agree almost entirely with his own, and that he therefore considers his experience sufficient to justify him in expressing an opinion, not only on those cases examined by him, but also "über jede andere Krebsgeschwulst."

The Calendar of the Imperial University of Japan for the year 1892–93 has been received.

The latest volume of the useful Aide-Mémoire Series, edited by M. Léauté, and published by MM. Gauthier-Villars, is on the "Choix et Usage des Objectifs Photographiques." The author is Prof. E. Wallon.

We have received a descriptive catalogue of the exhibits in the Anthropological Building of the Chicago Exposition. The anthropological laboratories contained three general subdivisions, viz. physical anthropology, neurology, and psychology. Sections were also devoted to growth and development, and to the anthropology of North American Indians.

A statement has been published of the origin, plan, and results of the field and other experiments conducted on the farm and in the laboratory by Sir J. B. Lawes, at Rothamsted, for the last fifty years. To the general statement are appended lists of the titles of all the published papers dealing with Rothamsted work, with full reference to the journals in which they appeared.

Mr. S. H. C. Hutchinson, the Meteorological Reporter for Western India, has sent us a brief sketch of the meteorology of the Bombay Presidency from April, 1892, to March, 1893, inclusive. The year 1892 was one of barometric minimum, and consequently one of excessive rainfall throughout the whole of the Presidency. In some respects the meteorological conditions resembled those of 1878.

Pathologists will welcome the publication of a new "Descriptive Catalogue of the Anatomical and Pathological Specimens in the Museum of the Royal College of Surgeons of Edinburgh," vol. i. In this volume the specimens which exemplify affections of the skeleton and organs of motion are described. A subsequent volume or volumes will include specimens relating to the alimentary canal, the respiratory system, &c. Mr. C. W. Cathcart, the Conservator of the Museum, deserves the thanks of all members of the medical profession for his useful and carefully compiled work.

The *Bulletin* recently issued by the committee for the execution of the photographic star-map, contains Prof. Kapteyn's investigations on the systematic differences between the photographic and visual magnitudes in different parts of the sky. M. Loewy contributes his second memoir on the construction of the catalogue founded on the *clichés* of the star-chart, and M. Prosper Henry describes the methods of measurement and reduction of the *clichés* for the catalogue, adopted at the Paris Observatory.

'A monograph of the North American Proctotrypidæ," by Mr. William H. Ashmead, forms *Bulletin* No. 45 of the U.S.

National Museum. In it is given a systematic description o the species of the hymenopterous family *Proctotrypidæ* found north of Mexico; the genera of the world being also studied and described, as an aid to future students. The Proctotrypidæ are considered by some authorities to be closely allied to the Chalcididæ, which they usually follow in catalogues and lists of hymenopterous families. Mr. Ashmead considers, however, that there is little affinity between the two, and that such an arrangement is unnatural. He thinks that the Proctotrypidæ should be placed at the head of the Terebrantia, for after the removal of the group Mymarinæ (which probably forms a separate and distinct family allied to the Chalcididæ), there is no relationship with the Chalcididæ.

THE first volume of "Studies from the Physical and Chemical Laboratories" of the Owens College has been published, and it furnishes evidence of the large number of important investigations carried on by the alumni of the College. The volume contains thirty papers in all, most of which have been reprinted from the Transactions and Proceedings of various societies. A paper by Mr. J. A. Harker, "On the Reaction of Hydrogen with Chlorine and Oxygen," has been translated from the *Zeitschrift für Physicalische Chemie*, and appears in English for the first time. Among the papers not previously published is one "On New Forms of Stereometers," by Mr. Haldane Gee and Dr. Harden, and another "On the Duration of Chemical Action in the Explosive Combination of Gases," by Dr. Turpin. The council of the Owens College has done a good work by collecting and publishing the results of researches made in its laboratories during the last few years.

IN his paper on the "Glacial Striæ in Somerville," Mr. Upham concludes, from a large series of observations, "that the currents of the ice-sheet were deflected here from one course to another, and even to several successive courses in so short a time that it allowed no great amount of erosion of the rock beneath." The general motion of the ice-sheet during the period of its maximum thickness was south-south-east over the Boston area, but it was deflected eastward during the recession of the ice. The long axes of the drumlins have also an eastward direction, and Mr. Upham finds in this fact evidence that they were formed wholly during the time of deflected glacial movements.

SINCE the publication, in 1868, of Pasteur's classical work, "Études sur le vinaigre," the only contributions of importance to this subject are those made in this country by Mr. Adrian Brown. It is, therefore, interesting to learn that Dr. Lafar intends devoting special attention to the whole question of the fermentation of vinegar, and the *Centralblatt für Bacteriologie*, vol. xiii. p. 684, 1893, contains his first contribution to, as well as a short review of, the existing literature on this important subject. In the course of his researches at the Institute for the Experimental Investigation of Fermentation Industries near Stuttgart, Dr. Lafar obtained a species of yeast which rendered beer strongly acid, and on studying its behaviour in other alcoholic media it was found to produce vinegar. The various observations made with this interesting organism are conveniently brought together in a table, and include the determination of the amount of vinegar produced, the changes, both in taste and smell, induced in the media, the formation of surface-film, &c. In his next communication, Dr. Lafar hopes to furnish more exact particulars of the physiological and bacteriological characters of this vinegar-producing yeast.

THE *Illustrated Archæologist* for December contains a number of very fine illustrations. Among the articles is one "On the Excavation of a Pictish Tower in Shetland," by Mr. G. Goudie. The author thinks that the remarkable round towers with the remains of which the islands of Orkney and Shetland are studded may be assigned a date as far back as the commencement of the Christian era, or earlier. Mr. Arthur Elliot writes on "Some Old Towers at Liège," and Mr. J. Romilly Allen, "On the Celtic Brooch, and how it was Worn." Dr. R. Munro contributes some notes on flint saws and sickles, in which he discusses the differences between Egyptian sickles and the saws found in the Polado lake-dwelling near Desenzano. He is of the opinion that there is little or no evidence that such sickles were in use among the prehistoric people of Western Europe, though compound saws of the kind discovered at Polado may be found among the *débris* of prehistoric civilisations beyond that of the lake dwellings of Europe.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Sir F. D. Dixon-Hartland, Bt., M.P.; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. Kenelm Chandler; two Arctic Foxes (*Canis lagopus*) from the Arctic Regions, presented by the Duke of Hamilton, K.T.; a Red Kangaroo (*Macropus rufus*) from Australia, two Short-toed Eagles (*Circætus gallicus*) European, deposited; a Moloch Lizard (*Moloch horridus*) from Australia, presented by Mr. John Carter.

IN line four of article "Experiments on Flying" (NATURE, December 14), read $n^{\frac{7}{2}}$ instead of n^7.

OUR ASTRONOMICAL COLUMN.

COLOUR-ABERRATION OF REFRACTING TELESCOPES.—At a recent meeting before the Royal Astronomical Society, the proceedings of which will be found in the *Observatory* (No. 208, December), Mr. H. Dennis Taylor read an abstract of a paper entitled "The Secondary Colour-Aberration of Refracting Telescopes in Relation to Vision," which had for its aim the determination of the detriment to vision, if any, and the percentage of light lost for defining purposes, owing to the presence of the usual colour-aberrations. In the colour curves which the author exhibited, where the wave-lengths and longitudinal colour-aberrations were represented by the ordinates and abscissæ respectively, some remarkable facts were brought to light. A comparison with Captain Abney's curves of the luminous intensity of the normal solar spectrum gave a means of obtaining a rough estimate of the percentage of light thus lost. The following table gives one a rough idea of these losses for different objectives in the case of star work, 100 representing the whole amount of light transmitted:—

Objective.	Focal length. Feet.	Light lost.
36-inch Lick Telescope	57	27
24 ,, Refractor	30	42
12 ,, ,,	15	21
6 ,, ,,	7½	9
28 ,, Greenwich Refractor	28	50

Other conclusions which the author draws from the above inquiry may be stated as follows:—In large telescopes the light-gathering power for star work by no means increases as the square of the aperture, the focal length being constant, but a point is reached when it increases simply as the aperture. With a given large aperture the light-grasping power can be considerably augmented by increasing the focal length. In the case of large telescopes, a smaller telescope of relatively large focal length may actually excel in light-grasping power a telescope of larger aperture and shorter focal length. In his concluding remarks Mr. Dennis Taylor refers to the increase of size in the images of stars under increasing exposures; this, he says, can be accounted for by the photographing of the halo of wasted light which surrounds the real image. If further research corroborates the views above stated, there seems to be no doubt that there is still room for improvement in rendering our lenses more perfectly achromatic. Of course the main point in large telescopes is to have them as short as possible, and it is satisfactory to notice the comparative smallness of the light lost in the 36-inch Lick instrument.

STARS WITH REMARKABLE SPECTRA.—The present list (*Astr. Nach.* No. 3200) is a continuation of that which appeared in a previous number of the same journal (*Astr. Nach.* No. 3171).

Among some of the *more* remarkable spectra may be mentioned that of R. Coronæ, which, as Mr. Espin says, is one of the most puzzling in the heavens. The spectrum, he "feels pretty sure," is a double one, and that there is a displacement; at one time the spectra coincide and the star's light is continuous, and at another they are so displaced as to give the appearance of bright lines flanked with dark ones. T. Coronæ, which showed some years ago a nebular spectrum, seems to have undergone a change, as Mr. Espin says that it "is certainly not now the case."

A remark of interest is that the region bounded by the declinations +51° and +56°, and R.A. 10h. 40m. and 11h. 8m. contains a large grouping of coloured stars. Out of 108 stars above 9th mag. there are seventeen which may be classed as orange-red. The region from β to ϵ Ursæ is also "very rich."

"Himmel und Erde" for December.—In the current number of this journal Prof. Scheiner contributes an interesting article on the cluster in Hercules; it is accompanied both with early drawings of this fine object as viewed in the telescope, and also with the latest photograph. The last-mentioned appears, as one would suppose, as if quite another object had been photographed, so different is the result obtained. Dr. Schwahn treats in a clear manner also of a very difficult subject in an article entitled "Die Lothabweichungen und das Geoid."

A New Variable.—In *Wolsingham Observatory Circular*, No. 38 (December 14), the Rev. T. E. Espin announces that photographs taken with the Compton telescope show that the star Espin-Birmingham 57' (R.A. 11h. 39m. 58s.; Decl. +56° 23'), Magnitude 9·5, is variable. The star is now 8·5 mag. It has a Type III. spectrum.

GEOGRAPHICAL NOTES.

Dr. F. A. Cook has communicated to the American Geographical Society of New York a scheme for the exploration of the Antarctic regions. He proposes to purchase a steam-whaler of 300 tons, equip her specially with several large boats, sledges, and an outfit similar to that used for Arctic travel, including fifty Eskimo dogs. The plan proposed is to steer south from the Falklands to Terre Louis Philippe, and enter the ice-barrier at the first convenient opening where winter quarters may be established and a landing effected. The adjoining land would be systematically explored and all possible scientific observations made. The scientific party will not exceed twelve or fourteen. Dr. Cook has had some experience in Arctic exploration with Lieutenant Peary, and Astrup, now with Peary on his second sojourn in North Greenland, has agreed to accompany him. It is proposed that the expedition should be one year in the Antarctic regions. Dr. Cook estimates the cost of his expedition at £10,000, which he hopes to raise by private subscriptions, grants from scientific societies, and by lecturing. While recognising the greater advantages to science likely to accrue from a national expedition on a large scale, such as that suggested by Dr. Murray, we would like well to see Dr. Cook's party also in the field, which is a wide one, and full of scientific possibilities.

Reuter's Agency announces that Mr. and Mrs. Theodore Bent and their party left Aden on the 16th inst. for the seaport of Makalla, on the south coast of Arabia, whence they will proceed to the interior with the object of exploring Hadramant.

Ausland announces the sudden death, on November 21, in Yokohama, of the Austrian Consul-General, Gustav von Kreitner, who was with Count Szechenyi on his great journey in Central Asia as topographer. There his work was of the best quality, and made the results of the expedition permanently valuable to cartographers.

The *Annales de Geographie*, a quarterly geographical paper edited by MM. Vidal de la Blache and Marcel Dubois, which has just entered on the commencement of its third volume, has already taken the first place amongst French geographical journals for the comprehensive scope of its contents and the solid value of the contributions to geography which it publishes, as well as for the impartiality of its editorial notes. The last number is particlarly good, containing a coloured map of the faunal divisions of the globe, with a discussion by Prof. J. Welsch; an able treatise on the lakes of the Jura by Dr. A. Magnin, several excellent studies in local geography, an epitome of M. Maistre's great journey to the Shari, and an account of Mount Ararat by M. Chantre.

The prospective formation of a "buffer-state" between Siam, Burma and China, necessitates a more complete survey of the region than has hitherto been attempted, and an Anglo-French Commission will probably undertake this work at an early date.

Dr. H. R. Mill completed a course of twelve lectures on geography applied to commerce, at the London Institution, on Tuesday evening. The lectures were arranged by the Royal Geographical Society as a special educational course, designed to meet the wants of merchants and advanced school-teachers. The first six lectures took up the scientific basis of commercial geography, showing the relations of mathematical, physical, biological, anthropological, and political geography to the special subject. The remainder of the course dealt with the commercial geography of the larger divisions of the British Empire, in order to enforce the general principles in particular cases. The attendance throughout was satisfactory; and the same course was given on Friday evenings at Birmingham, under the Oxford University Extension scheme. Mr. Mackinder will commence the second course of educational lectures for the Royal Geographical Society on January 12, in the hall of the United Service Institution, Whitehall, the subject being the relation of geography to history.

A NEW PROCESS FOR THE PREPARATION OF ETHERS.

A new and advantageous general process for the preparation of ethers (alkyl oxides), including the most important from a technical point of view, ethyl ether, is described by Prof. Krafft, of Heidelberg, in the current *Berichte*. In the course of an investigation of the aromatic derivatives of sulphuric acid, it was observed that there is a complete analogy between the behaviour of sulphovinic acid and its homologues on the one hand, and the alkyl esters of aromatic sulphonic acids on the other, towards alcohols at moderately elevated temperatures. It was found, in fact, that the conclusions arrived at by Prof. Williamson in the year 1851, with regard to the processes involved in the formation of ethers from the esters of sulphuric acid, are equally applicable to the alkyl esters of the sulphonic acids. For these latter substances decompose in a precisely similar manner to the alkyl sulphuric acids upon warming with alchols, an ether being the product of the reaction. Thus, for instance, the reactions between alcohol and ethyl sulphuric acid, and between alcohol and the ethyl ester of benzene sulphonic acid, run exactly parallel, as will be apparent from the equations representing them—

$$HO.SO_2.OC_2H_5 + C_2H_5OH = HO.SO_2.OH + C_2H_5.O.C_2H_5.$$
$$C_6H_5.SO_2.OC_2H_5 + C_2H_5OH = C_6H_5.SO_2.OH + C_2H_5.O.C_2H_5$$

This new class of reactions of the sulphonic acids appears likely to prove of more than merely theoretical interest, for on account of the great stability of these aromatic substances, they are capable of converting far larger relative quantities of alcohol into ether when the reaction is made continuous than the alkyl derivatives of sulphuric acid. Although sulphuric acid is so cheap, and the manufacturing process of continuous etherification has been rendered as perfect perhaps as is possible, still oil of vitriol is unfortunately prone to decomposition in contact with a readily oxidisable substance such as alcohol, becoming reduced to sulphur dioxide which is lost in the gaseous state. Moreover, the powerful affinity of oil of vitriol for water, which is one of the products in the first stage of the reaction, brings about such a dilution after treatment with a considerable quantity of alcohol, that it is no longer capable of performing its function in the process of etherification, which latter must of necessity be arrested in order that the acid may be replaced. Now, the sulphonic acids of the aromatic series, such as benzene sulphonic acid, $C_6H_5.SO_2.OH$, are so stable at the temperature of reaction with alcohol, that the latter is only etherified, and not in the slightest degree oxidised, doubtless owing to the fact that the hydroxyl group present in sulphovinic acid is replaced by the less mobile radicle of the benzene nucleus. Further, the water which gradually accumulates is not retained by the sulphonic acid, but passes over largely with the ether, from which it separates as a distinct layer in the receiver.

This mode of preparation of ethyl ether and its homologues from alcohols by means of sulphonic acids may therefore be very advantageously substituted for the ordinary process now in use. It may be carried on in a perfectly continuous manner, employing the same quantity of the sulphonic acid for weeks, in open vessels and upon any scale. There would appear to be practically no limit to the amount of alcohol which any definite amount of sulphonic acid is capable of converting into ether. Prof. Krafft has actually followed the process with benzene sulphonic acid until one hundred times its weight of alcohol had been so converted, and the residual sulphonic acid appeared as capable of bringing about the reaction, and as free from products of decomposition, as at first.

The reaction in the case of benzene sulphonic acid can readily be proved to occur in the two stages indicated in the following equations :—

$$C_6H_5.SO_2.OH + C_2H_5.OH = C_6H_5.SO_2.OC_2H_5 + H_2O\ ;$$
$$C_6H_5.SO_2.OC_2H_5 + C_2H_5.OH = C_6H_5.SO_2.OH + C_2H_5.O.C_2H_5$$

For if the process is arrested at any time and the liquid in the distilling vessel is poured, when cool, into water, the ethyl ether of benzene sulphonic acid, $C_6H_5.SO_2.OC_2H_5$, immediately separates in the form of a difficultly soluble heavy oil, which after separation is found to boil at 156° under 15 m.m. pressure, which temperature has previously been given by other observers as the boiling-point of the compound.

The benzene sulphonic acid may be replaced by benzene disulphonic acid, para-toluene sulphonic acid, β-naphthalene sulphonic acid, or any stable sulphonic acid or its esters.

As a laboratory or lecture experiment this new process of etherification may be easily carried out in the following manner :—The sulphonic acid, about 80–120 grams in quantity, is conveniently placed in a strong glass tube, 25–30 centimetres high and 5 centimetres wide, closed at one end. The open end is stoppered with a well-fitting ordinary cork bored with three holes, through one of which a thermometer is inserted, through another the tube leading to the condenser, and through the third the stem of a dropping funnel. The benzene sulphonic acid is first melted and then heated to about 135–145° with the thermometer in the liquid. Alcohol is then allowed to emerge into the hot liquid from the dropping funnel, whose stem is made to end in a fine opening only about an inch from the bottom of the reaction cylinder. The supply of alcohol is maintained constant at a convenient rate from a reservoir whose delivery tube passes air-tight through a cork in the neck of the dropping funnel. The two layers of ether and water then rapidly collect in the cooled receiver into which the tube of the condenser passes.

The process lends itself equally well to the preparation of mixed ethers. For instance, if a mixture of methyl and propyl alcohol are allowed to pass through a layer of a sulphonic acid, β-naphthalene sulphonic acid was used in the actual experiment made, at a temperature of 122–126°, the product consists largely of methyl propyl ether. This mixed ether, which has previously been found so difficult to obtain, and which is important as being isomeric with ethyl ether, can readily be obtained pure by fractional distillation of the product, when it is found to boil constantly at 37°. Similarly, di-methyl and di-propyl ether may be readily prepared from the corresponding alcohols. Isobutyl ether may also be obtained with ease from isobutyl alcohol by use of a sulphonic acid, a reaction which it has hitherto not been found possible to carry out by means of sulphuric acid.

A. E. TUTTON.

THE PROGRESS OF TECHNICAL EDUCATION.

SINCE the passing of the Technical Instruction Acts in 1889 and 1891, authorising County Councils to devote the funds accruing under the local taxation (Customs and Excise Act, 1890) to educational purposes, considerable progress has been made both as regards the number of authorities who have availed themselves of the provisions of the Act, and also in respect to the proper disposal of the funds. From the last report of the National Association for the Promotion of Technical and Secondary Education it appears that out of a total of 126 local authorities in England and Wales, 114 are now giving the whole, and twelve are giving part of the grant to educational purposes, and, estimating the total amount distributed at £750,000, no less than £604,000 is spent to this end. These figures show that the work of technical instruction is firmly established, and it only needs to be organised and consolidated to become a very important factor in our educational system.

It seems desirable, now that the scheme has had sufficient time to crystallise into shape, to put on record some of the experiences of Technical Instruction Committees, as set forth in reports to various County Councils. By this means it is possible to give an idea of the developments which are most likely to end in good results. No attempt is made in the following to discuss all the reports, for such a course would be beyond the limits of this paper. A few reports have been selected, and from them extracts have been taken which are likely to be of use for future procedure.

For convenience we begin with the northern counties. The Northumberland Committee reports that—"The average attendance at the science classes was not quite as satisfactory as might have been anticipated. It is notable, moreover, that the centres where the attendance was smallest were not always situated in sparsely populated districts. On the contrary, in more than one fairly populated district, where educational work of a similar character has been carried on for some years, and where a general and ready appreciation of the advantages offered might reasonably be expected, the results were disappointing. In several instances the teachers experienced difficulty on account of the lack or diversity of the previous training of the students, and it is to be hoped that the more general establishment of night schools and continuation classes will, in the course of time, prepare the ground for the work of the special technical instructors."

In thus expressing the need for more schools to prepare the ground for technical instruction, the committee shows its good sense. Elementary science is the best foundation of a technical education, and to attempt to infuse a knowledge of technicalities into the minds of the young mechanics of this country without such a preliminary grounding, is to court failure. The action of the Department of Science and Art, in withdrawing grants for second-class certificates, was taken in order to force the Technical Instruction Committees to provide the necessary elementary instruction. Unfortunately, however, some committees have not yet realised their duty in this matter, so between them and the Department many classes in elementary science have fallen to the ground.

One of the greatest needs experienced by Northumberland is for a good secondary school. To quote the report: "The facilities for secondary education in Northumberland are in certain parts of the county entirely absent, and where they do exist appear to be in many cases inadequate, inefficiently equipped. and having no relation to the established agencies for elementary and higher education. In the south-west of the county there is no secondary school of any description, and the lad who gains a scholarship has no choice between Newcastle and Carlisle. . . . . Of the schools of a secondary character already in existence in the county, in only one or two cases is there any attempt to provide systematic instruction in science, and in no case is there, outside Newcastle, laboratory accommodation for practical work in chemistry or physics."

This is a very regrettable state of things, and much progress cannot be made until it is altered. A good secondary school should be established at every large centre of population. There are, however, numerous large districts not so favoured. For example, the Technical Instruction Committee of the West Riding of Yorkshire, which is without doubt doing as good work as any committee in the country, reports that in the Todmorden district, with a population of over forty thousand, the nearest available secondary schools are at Halifax, more than twelve miles away, and there are many districts in other counties far worse off. Clearly a portion of the sums now spent in the railway fares of holders of scholarships would be better expended in the establishment of secondary schools in the required districts, or by increasing the scholarships to the amount necessary to cover the cost of maintenance of the scholar at a residential college. The payment of the West Riding Committee for railway fares during the year covered by the last report amounted to nearly £4000, of which about £3000 was expended under the scholarship scheme. This money would be better spent in subsidising local technical schools, and the committee intends in the future to follow such a course as far as possible.

It has been remarked that the Department of Science and Art is throwing its responsibility to some extent upon the County Councils. The West Riding Committee estimates that by the withdrawal of grants for apparatus and second-class students, an expenditure of more than £3,500 has been shifted to their Yorkshire Council. It is justly complained that "the changes have been carried out without in any way considering the views of the County Council. It is clearly necessary that some distinct understanding should be arrived at as to the spheres to be respectively occupied by County Councils and the several Government departments, including the Education Department, the Science and Art Department, and the Agricultural Department, or it may be found that the funds specially granted to the County Councils for the purpose of technical instruction are being largely absorbed in carrying out the work hitherto devolving upon Government departments."

To some extent, however, the departments referred to are completely justified in their action. Thus, instruction in elementary science can very well be relegated to local authorities, and so leave the Department of Science and Art to foster more advanced work. This brings us to another point, viz. the system of payment by results. Any other system involves the employment of a large staff of inspectors, and the question then arises as to whether the close inspection required ought to be carried on by the County Councils or by Government officials. It is the opinion of many directors of technical instruction that a Government official is in a better and more independent position for doing such work than a county official. Usually the work of inspection done on behalf of most counties is small. In the case of the West Riding Committee a number of inspectors have been appointed, and the grants made to classes, schools, and institutions under its jurisdiction take the form of capitation grants, depending, not upon the instruction given, nor upon the number and size of the classes at each school or institution, but upon the attendance and work of the individual pupils and students. This admirable system is certainly worthy of extended application.

The Union of Lancashire and Cheshire Institutes has done much to promote primary, secondary, and technical education in Lancashire, Cheshire, and North Derbyshire, and to consolidate the various associations that exist in those counties. The Union acts as an examining board, and offers special prizes and exhibitions for the encouragement of science and art. As evidence of the importance of the Union, and the great activity shown in the cause of technical and secondary education, it is sufficient to say that 128 institutes are affiliated to it, with a membership of over 100,000, and upwards of 80,000 students attending evening classes, and at the examinations held this year 10,700 papers were worked. These facts are enough to indicate that the Union has become an important examining authority in Lancashire and Cheshire. It is satisfactory to know, therefore, that the governing council fully recognises the necessity of good teaching and a thorough systematic scheme of education. It is to some extent owing to the existence of this Union that Lancashire ranks among the counties doing the best educational work. Cumberland and Durham are also developing excellent and comprehensive schemes of instruction.

Passing now to the southern counties, we find that Kent has been largely spending its money upon University Extension Lectures. The following extract from a report of one of the lecturers is therefore of interest:—

"Although the last two years' experience in Kent must have convinced all of the great possibilities of technical education in rural districts, yet at present the success is but partial, and the results ephemeral, owing to the isolation and want of continuity of the various educational ventures in process of trial. To achieve real educational results, local classes under local teachers should be formed in each village centre. Laboratory accommodation of a simple and inexpensive nature should be provided, and from time to time a course of lectures by an experienced lecturer might supplement the local class, and serve to arouse general sympathy, interest, and enthusiasm.

"Most emphatically would I urge, with the whole conviction of past experiences, the absolute necessity for practical laboratory instruction as a part of any scheme for the teaching of chemistry. To make technical education a real servant to the national weal, and a sound branch of educational progress, it will be necessary to connect, systematise, and unify the varied educational machinery employed. The successful founding of village laboratories and classes, under capable instructors, will make it possible for a village lad to place his foot upon the first rung of a ladder that will raise him through urban technical institutes or county colleges to the higher levels of scientific and technical instruction.

"As an extension lecturer, I feel bound to confess that, standing alone face to face with the problem of technical education in rural districts, our present system is doomed to failure unless supported by an adequate system of local teaching, and, as a student of science, I feel convinced of the absolute impossibility of imparting an intelligent group of scientific principles capable of practical application and utility unless such instruction be supplemented by courses of practical and experimental study."

This is a right view to take. The function of the extension lecturer is that of a pioneer in the case of science, whatever it may be with literature. There is no doubt that in the classes held after extension lectures, the lecturer assumes more the part of a teacher by being brought into closer contact with the students, but even then it is doubtful whether he is often regarded as more than a popular exponent of elementary principles.

The Technical Instruction Committee of the Surrey County Council is a very strong one, and its efforts have been attended with a remarkable measure of success. In the tenth report of the committee, however, it is remarked with regard to the science classes: "There is probably no branch of the work more educationally important than this, and in Surrey, as in other counties, it has been found that there is none which meets with more passive opposition from the public, and, perhaps, costs more, in consequence of the entire lack of efficient teachers in the localities themselves." We are afraid that this is very true. That undefinable quantity—the general public—may attend science lectures of which the main features are magic-lantern illustrations, or explosions and pretty experiments; but that is quite a different matter from attending classes requiring close study. We do not for an instant hold that popular science lectures are not productive of good. By their influence the commonality are brought to know something of the poetry of science, and are set thinking about nature's laws and wonders. What we do contend, however, is that such discourses must be regarded as of a recreative character, calculated more to interest and amuse than to give a clear view of the true inwardness of scientific things. The general public wants variety and highly-coloured facts, and a very small proportion indeed are inclined to take upon themselves the drudgery of hard study. Technical Instruction Committees should remember, therefore, that though the attendance at classes may be small in comparison with that at lectures, the students are mostly workers who take up science seriously, and with the full knowledge that many difficulties must be met and overcome. It is upon this class of the community that all schemes of technical instruction depend for their success. As to the second point raised in the above extract, there is little doubt that, in many counties, peripatetic teaching by good teachers, who can be obtained by the payment of a good salary, is preferable to entrusting the instruction to local dabblers in science. This applies chiefly to country districts in which science was almost unheard of before the County Councils began their educational work.

In the last scholarship report of the Surrey Committee, Mr. Macan, the organising secretary, makes a gratuitous remark that can by no means be substantiated. He says: "The subjects which require most attention in the schools appear to be chemistry, heat, and electricity, and masters are reminded that the purely bookish and routine instruction, which serves to gain South Kensington results, is not enough for a scholarship examination." This is a cheap criticism that might well have been omitted. Any teacher who has had experience of the South Kensington examinations knows that great stress is laid upon the practical teaching of the subjects named, and examiners are expressly forbidden to award marks for meaningless phrases such as are given by candidates with mere book knowledge. And we will say further, that any candidate who could pass the elementary examinations in chemistry, heat, or electricity, held by the Department of Science and Art, would come off with flying colours in the scholarship examination of the Surrey County Council. There is not a single question upon these subjects contained in any of the examination papers of the Council but what a departmental examiner at the present time would consider too elementary for South Kensington candidates.

The work of the Berkshire Technical Instruction Committee has been greatly facilitated by the establishment of the University Extension College at Reading. The college possesses good teachers, and, owing to the proximity of Reading to London, and the special relations which the college has to Oxford, the services of specialists can easily be obtained to supplement the teaching of the regular staff. For the sum of about £300 per annum paid to the college, systematic instruction is given to teachers in elementary schools at four centres. The scheme followed provides an excellent graduated course extending over three years, and given by well-qualified instructors. An agricultural department, such as exists at Bangor, Leeds, and Newcastle, has been added to the college, so that it will not be necessary to send students holding agricultural scholarships out of the county for their instruction. The establishment of University Extension colleges at strong centres is certainly an admirable plan, and County Councils would do well to assist in their foundation and adequate equipment.

An important report upon the relation of secondary schools to a county scheme of technical education has been prepared for Southampton county by Mr. Vaughan Cornish, and adopted by the Technical Instruction Committee. The fact is recognised that it is of little use to make provision, by scholarships or otherwise, for the highest forms of technical training unless there are schools which provide such an instruction. Hampshire at present possesses very few schools of this kind, but the committee proposes to assist, by means of capital grants to improve the appliances for teaching, by capitation grants, and by scholarships, the public secondary schools in the county that are able to give an efficient general preparation for an industrial (*i.e.* manufacturing, agricultural, or commercial) career. Something can be said in favour of this scheme, but great care will have to be taken in the selection of the schools, or the funds may be misapplied.

From the report of the Wiltshire Technical Instruction Committee, it appears that that county shows a lower standard of general elementary education than that of almost any county in England. On this account, the majority of the students are not fit recipients of higher or technical education; and the fact that very few technical or secondary schools exist within or in the near neighbourhood of Wiltshire, has rendered the work of the committee most difficult. It has been necessary to create as well as foster a desire for technical education. In this connection the following extract from a letter addressed to Lord Fitzmaurice by Mr. Ashenhurst is of interest :—

"It must be borne in mind that mathematics are the real foundation on which technical knowledge alone can be built up, and I am fully convinced in my own mind that intending students seeking instruction in the different technological subjects, for the teaching to be of any practical use to them, they must of necessity study the above-mentioned subjects. Until such times as classes for the study of the higher branches of arithmetic and mathematics are established, it is almost useless for the committees of different technical schools in the county to expect a large number of students to derive advantage from the various subjects being taught in technology.

"These remarks are based upon the fact that, personally, I have been obliged to teach arithmetic before the students could make the necessary calculations for the branch of textile industry I am now particularly engaged to teach, viz. cloth weaving and designing.

"Had such institutions as the Mechanics and Working Men's Institutes, which have been so prevalent in the large towns and villages of the North for this last thirty or forty years, been established in this district, where evening classes could have been held for instruction in elementary subjects, the educational standard of this county would have held its own with that of any other in the United Kingdom."

But though the committee has had to labour under such difficult conditions, and has made some mistakes (which was inevitable, perhaps, under the circumstances) it has worked energetically and well in initiating and fostering technical education in Wiltshire, and it has evolved a system of instruction that ranks in point of excellence even with that of any northern county.

The real object and scope of technical education is thus stated by the Devon County Council :—

"It is not contended that technical education will prove a panacea for all the evils resulting from the depression of trade and agriculture, or that it will remedy all the difficulties arising from foreign competition. But it is certain, that by due attention and reform in our educational methods, a good deal can be done to remove some of the more serious defects under which our industries are at present carried on.

"Technical education has been described as being not so much a specific subject, or group of subjects, as a *method*. It is concerned with the 'why' and the 'wherefore' and the 'how.' It enables workmen to develop their faculties, to obtain a knowledge of the principles underlying their work, and to get thoroughly practical information with regard to the materials and the tools which they use. It provides a means for the training of the eye and hand, and encourages dexterity, neatness, and order; and while not in any way antagonistic to book learning, it relies to a great extent upon handwork rather than upon headwork. It does not, however, involve the teaching of the practice of a trade or industry, or the drilling of individuals as apprentices would be drilled."

This certainly reads very well, and may be taken as a sign that Devonshire is at last beginning to work on good lines. We notice with some regret, however, that the committee has decided to relegate some of their powers to District Committees. The whole provision of technical instruction is to be in the hands of (1) the County Technical Education Committee; (2) the District Committees, who are responsible to the County Technical Education Committee; and (3) the Local or Parish Committees, who are in turn responsible to the District Committees. The general opinion of those who ought to know is that the system of District Committees or Divisional Committees is a hopeless blunder. Such bodies may be of use for advising purposes, but when money has been allotted to them for distribution, it has generally led to inefficient and extravagant expenditure. It is satisfactory to learn that the instruction in the technical and the science and art schools of Devon is increasing in comprehensiveness, but there is yet much room for improvement. The last report shows that all the schools devote considerable time and energy to art, but few of them take up an adequate number of science subjects.

The committee of the Cheshire County Council does not institute classes, but make grants to various centres to carry out class work. A staff of lecturers is kept engaged in visiting various places, and giving series of lectures on subjects mostly connected with agriculture. Grants are made to grammar schools, and considerable subsidies are given to various bodies for building purposes. In addition to these grants, most of the town councils and local boards in Cheshire tax themselves for technical instruction purposes. The county also possesses a comprehensive scholarship scheme. It seems a pity, however, that the committee does not pay more attention to the teaching of the rudiments of science, instead of concentrating their energies almost entirely upon "bread and cheese" subjects.

Before the Technical Instruction Act came into operation, Shropshire had done very little to foster education of any kind. It is not at all astonishing, therefore, to learn that much of the early work of the Technical Instruction Committee was futile. In 1892 the scheme for agricultural and science scholarships completely failed; six were offered of the former, and ten of the latter, but though the examinations were well advertised, only one candidate entered his name, and he failed to obtain half the total marks adjudged to the papers set. There was also a very limited competition for the exhibitions and scholarships offered this year; indeed, the results have been so unsatisfactory that the committee has rescinded the original scholarship scheme and substituted another. Salop is not alone in this respect, for quite a number of counties have had a difficulty in producing candidates for their scholarships, to their discredit be it said. The committees of these counties will have to work for many years before they bring their charges up to the standard of counties like Yorkshire.

The work of technical instruction carried on in Somerset is based upon broad lines, and is extending. From the outset, however, the task of the committee has been made more difficult by the almost complete absence of fully organised schools of science and art, the absence of any adequate provision for science or technical training in the secondary schools, and the consequent inefficient previous education and training of those who have attended the classes in special technical subjects. It was to be expected in such a case that University Extension lectures should be found a satisfactory means of reaching the adult population, and also of great service in creating an interest

in science and in technical instruction generally. The Somerset committee is laying an excellent foundation on which to erect a permanent and comprehensive system of technical education, but some time must elapse before the structure will be seen and properly appreciated by the county. The following extract shows that the committee realises the importance of instruction in elementary science and mathematics:—

"It is the boys at present at secondary schools who will in time become directors and leaders of industries, agricultural or otherwise, and from whom improvements in our various industries ought to come. The best way to prepare them for their future career, and to equip them for their struggle against foreign competition, is to begin whilst they are still at the secondary schools, and give them a sound general education, including a large proportion of science and mathematics. They will thus learn something of the method of experiment and of the manner in which knowledge is acquired, their powers of observation will be cultivated, and their judgment to some extent trained, and they will learn to see much more clearly than at present the intimate relation between science and their daily life and occupations.

"It seems certain that the only way in which a real appreciation of the value of technical instruction in agriculture can be created is to provide for the coming generation of farmers a sound training of the character indicated. In this connection it may be well to call attention to a statement made by Prof. Fream, in his report on technical education to the Royal Agricultural Society of England, that his own experience, extending over many years, shows that a boy who is 'fairly competent in mathematical studies,' is as a rule very good material to work upon in giving instrucion in the principles and practice of agriculture. To mathematics, from this point of view, natural science may unquestionably be added.

"At present it must be admitted that the science teaching in the secondary schools in Somerset has not reached the degree of excellence and thoroughness that is desirable, and in some instances the teaching of mathematics is capable of considerable improvement. There is at present no school in the county at which higher scholarships under the Technical Instruction Acts could fitly be made tenable."

Staffordshire did excellent work in the cause of technical education before the passing of the Technical Instruction Act, and since then it has taken the initiative in many important developments. Both last year and this, a number of teachers in elementary schools received grants towards the expense of a course of manual instruction in wood-work, metal-work, and cardboard-work at Dr. Götze's institute in Leipzig, and most of them are now conducting classes in the county. This system cannot be too highly commended, and is worthy of adoption by every county; for by it new methods of work will be learnt, while the insularity that characterises the British workmen will be removed.

Like many other counties, Oxfordshire has to lament the want of an adequate number of secondary and technical schools. On this account it has been found difficult to arrange for the further education of holders of county scholarships. Notwithstanding these serious defects, however, the committee reports that, taking the county as a whole, secondary and technical instruction is in a state of increased efficiency. In common with other committees, that of Oxfordshire sent in 1892 a number of teachers to attend the summer courses on geology, chemistry, botany, and mechanics, arranged at Oxford by the delegates for the extension of University teaching, and with most satisfactory results. A similar summer course for County Council students was held this year, the subjects and the lecturers being:—Geology, Prof. A. H. Green, F.R.S.; Practical Physics, Rev. F. J. Smith; Hygiene, Dr. C. H. Wade; Chemistry, Mr. J. E. Marsh; Animal and Vegetable Pests of Crops and Stock, Mr. P. Chalmers Mitchell and Mr. J. B. Farmer. The success of these short courses indicates that it may be desirable for counties to grant scholarships which would enable students to reside in University towns during term, and take advantage of the many facilities for study available at these centres of learning.

No reference has yet been made to the county boroughs. This survey would not be complete, however, without a few words on the work done in some cities. Oxford city, for instance, has a very strong Technical Instruction Committee, and the work accomplished during the last session shows a very considerable advance upon that of the previous year.

The city of Liverpool possesses a scheme of technical instruction that connects educational institutions from the elementary schools up to the University by means of scholarships and free studentships, and is thus a true educational ladder. The technical instruction is controlled by a sub-committee of the Liverpool Library Museum and Arts Committee. Before this sub-committee came into power, much of the work of technical instruction previously carried on in the city was supported by voluntary contributions, but these were largely withdrawn as soon as public money became available for the purpose. Owing to the loss of income due to this cause, and that which has resulted from the withdrawal of grants by the Department of Science and Art, and the City and Guilds of London Institute, a large portion of the funds set apart by the Council for purposes of technical instruction has to be used in supplying these deficiencies. But in spite of this, new branches of work have been developed, and in a very short time the whole scheme of the sub-committee will be in successful operation. A nautical college has been established, and from the last report of the head-master, Mr. James Gill, it appears that an astronomical observatory is to be erected in the school-yard, which will serve to create a greater interest in nautical astronomy and the almanac by reference to the aspects of the heavens, revealed by the telescope, and the astronomical methods of measuring time. For completeness of equipment and suitability for the work of technical and scientific nautical instruction, the college compares favourably with any of the same kind in the world.

The borough of Bootle has the distinction of being the first to take advantage of the Local Taxation Fund for technical instruction. The instruction provided in the borough is of the right kind, and should lead to good results.

The first report of the Technical Instruction Committee of Plymouth shows that progress is being made. That the demand for technical instruction is increasing in this borough is evidenced by the fact that though a fine school was opened last year, the building will have to be extended in order to provide the necessary accommodation for students.

It is beyond the scope of this article to refer to the numerous institutes and schools, such as those of Manchester, Birmingham, Bradford, Bristol, and Bolton, that existed before 1889, and made provision for technical instruction. The towns that possess these old-established educational agencies are necessarily far ahead of those that have only recently had the importance of technical instruction thrust upon them. It will have been gathered from the foregoing description that the greatest need felt by newly-constituted authorities is for technical and secondary schools. Not until this want has been supplied, either by subsidising existing schools or building new ones, can many of the County Councils hope to see the fruits of their labours. The policy of withdrawing grants for elementary instruction in science, recently taken by various examining authorities, has been the means of raising the standard of efficiency in counties where science classes have been held for many years. In some counties, however, the committees have not realised that it is their duty to provide elementary scientific instruction; for they are using their funds almost entirely in supplying instruction in industrial "dodges." On the other hand, it is becoming recognised that science students must possess a more extended knowledge of mathematics than they usually have before any great advance can be made. No unbiassed observer can deny that the progress reported up to now has generally been in the right direction. Mistakes have, of course, been made, but the committees are usually not slow in seeing their failings, and rectifying them. In a few years, when the distrust and suspicion which hampers the work in some counties has been broken down, we shall have the nucleus of a system of education such as exists in Germany, France, and Switzerland, and shall begin to reap the benefits that accrue from it. R. A. Gregory.

SCIENTIFIC SERIALS.

Bulletin of the New York Mathematical Society, vol. iii. No. 2 (November, 1893, New York).—"Lachlan's Modern Pure Geometry" (pp. 33–36) contains a review, by Prof. F. Morley, of Dr. Lachlan's treatise. It mainly points out what the writer considers to be defects in the author's programme, but closes with the hope, since Dr. Lachlan shows so much power in handling his subject, that he will "throw examination

schedules to the four winds of heaven," and deal largely "with some part of the present outlook as stated in Klein's 'Vergleichende Betrachtungen.'" Prof. Cleveland Abbe gives (pp. 36–38) an analysis of papers on vortices in a compressible and rotating fluid, by Mr. Charles Chree, and trusts that the strictly meteorological work of his new position (at Kew) will tempt him to apply modern mathematical analysis to the winds, the clouds, and the storms of the actual atmosphere. Dr. T. Craig's high estimate of the Traité d'Analyse, by M. Émile Picard, will be seen from the space (pp. 39–66) he devotes to an account of this first volume. The extraordinary developments in the theory of functions, in differential equations, and in certain purely algebraical theories, and the important applications of the results of these developments to geometrical, physical, and astronomical problems, have made such a treatise almost indispensable. Notes and new publications occupy pages 65–72.

THE last volume of the *Memoirs of the St. Petersburg Society of Naturalists* (vol. xxiii.), for the Section of Botany, contains, besides the proceedings of the Society, a number of valuable papers. N. V. Diakonoff gives, under the title "Typical Representatives of the Life-substratum," a summary of his researches into the behaviour of lower fungi in an atmosphere devoid of oxygen. The *Penicillum glaucum* is a typical representative of organisms in which no life is possible without the action of oxygen; while *Mucor stolonifer* may be taken as a representative of organisms in which life is impossible without either the action of oxygen or the presence of a substance capable of fermenting. Prof. N. Tsinger gives a description of the mosses of Tula, of which 134 species are enumerated. M. L. P. Bowdin gives the results of his very interesting experiments upon the breaking out of buds upon cuttings of plants. S. G. Navashin describes and figures a new parasite of the cupsulæ of some mosses, *Tilletia* (?) *sphagni*. N. Aiboff gives the results of his five years' exploration of the flora of Abkhazia (on the north-east coast of the Black Sea); his collection numbers no less than 1300 species, and does not confirm the conclusion as to the flora of Caucasia, arrived at by MM. Krasnoff and Kuzeretsoff. S. Navashin gives a very elaborate paper on the Discomycete, *Sclerotinia betulæ*, with several coloured plates. The vegetation of t e Zerafshun valley is shortly described by V. K maroff; and N Ponyatsky criticises Hugo de Vries' method for the analysis of isotonic coefficients.

Bulletin de la Société des Naturalistes de Moscou, 1893 November 1.—On some ecto- and ento-parasites of the Cyclopides, by Dr. W. Schewiakoff. One new species, *Trichophrya cordiformis*, is described, as also the ento-parasitic slimes of the Cyclopides.—Note, by W. Zykoff, on the chorda of *Siredon pisciformis*.—Note on a new skull of *Amynodon*, by Marie Pavlow.—A catalogue of the Coleoptera of Kazan, by L. Krulikovsky: the Noctuæ.—On the evolution of the ocean, by H. Trautschold, being an attempt at tracing the gradual development and modification of salinity in the ocean throughout the earth's history.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 23.—"A certain Class of Generating Functions in the Theory of Numbers," by Major P. A. MacMahon, R.A., F.R.S.

The present investigation arose from my "Memoir on the Compositions of Numbers," recently read before the Royal Society and now in course of publication in the Philosophical Transactions. The main theorem may be stated as folows:—

If $X_1, X_2, \ldots, X_n$ be linear functions of quantities $x_1, x_2, \ldots, x_n$ given by the matricular relation

$$(X_1, X_2, \ldots, X_n) = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_n & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & n3 & a_{nn} \end{pmatrix} (x_1, x_2, \ldots, x_n),$$

that portion of the algebraic fraction

$$\frac{1}{(1 - s_1X_1)(1 - s_2X_2)\ldots(1 - s_nX_n)},$$

which is a function of the products,

$$s_1x_1, s_2x_2, \ldots, s_nx_n,$$

only, is $1/V_n$, where (putting $s_1 = s_2 = \ldots = s_n = 1$)

$$V^n = (-)_n x_1 x_2 \ldots, x_n^n \begin{vmatrix} a_{11} - 1/x_1, & a_{12}, & \cdots & a_{1n} \\ a_{21}, & a_{22} - 1/x_2 & \cdots & a_{2n} \\ \vdots & \vdots & & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} - 1/x_n \end{vmatrix}.$$

The theorem is of considerable arithmetical importance, and is also of interest in the algebraical theories of determinants and matrices.

The theory is developed at length in the paper, with illustrative examples of arithmetical applications.

Incidentally interesting results are obtained in the fields of special and general determinant theory. The special determinant, which presents itself for examination, provisionally termed "inversely symmetric," is such that the constituents symmetrically placed in respect to the principal axis have, each pair, a product unity, whilst the constituents on the principal axis itself are all of them equal to unity. The determinant possesses many elegant properties which are of importance to the principal investigation of the paper. The theorems concerning the general determinant are connected entirely with the co-axial minors.

I find that the general determinant of even order, greater than two, is expressible in precisely two ways as an irrational function of its co-axial minors, whilst no determinant of uneven order is so expressible at all.

Of order superior to 3, it is not possible to assume arbitrary values for the determinant itself and all of its co-axial minors. In fact of order n the values assumed must satisfy

$$2^n - n^2 + n - 2$$

conditions, but these conditions beings atisfied, the determinant can be constructed so as to involve $n - 1$ undetermined quantities.

"On the Whirling and Vibration of Shafts." By Stanley Dunkerley, Berkeley Fellow of the Owens College, Manchester

December 7.—"Reptiles from the Elgin Sandstone: Descriptio of Two New Genera." By E. T. Newton, F.R.S. Com unicated by permission of the Director-General of the Geological Survey.

Two new reptiles from the Elgin Sandstone are described in detail. One of them is the property of Mr. James Grant, of Lossiemouth. The bones themselves being absent, their forms have been reproduced by gutta-percha casts taken from the cavities left in the stone. This reptile was evidently allied to *Stagonolepis*; it is represented by the skull, which is about three inches long, and the anterior half of the body, with the pectoral arch and both the fore limbs. The skull is depressed, has a pair of large prelachrymal fossæ; the two nasal openings are small, and placed near the end of the muzzle. The palate is narrow and deeply grooved, with primitive posterior nares placed far forwards. The vertebræ and limbs are Crocodilian in form. Above the vertebræ there is a double row of pitted, and closely-set scutes. This small Parasuchian is named *Erpetosuchus Granti*.

The second specimen was obtained by the Rev. Dr. Gordon, from the quarry at Spynie. In this fossil the bones were present, and the skull is still preserved, but many of the other bones were too much crumbled to show their form, and the casting process was again resorted to. The neck and fore limbs are wanting. The skull, which closely resembles that of *Ceratosaurus*, is about $4\frac{1}{2}$ inches long, sharp anteriorly, and bird-like when seen from above, but deep when seen from the side, and it has a large prelachrymal fossa. The teeth are compressed and serrated anteriorly and posteriorly. The palate is deep, and a median pair of apertures, near the post-palatine vacuities, are believed to be primitive posterior nares placed far back. Many oval scutes are scattered above the neural spines.

This reptile seems to be intermediate between the Dinosaurians and Crocodilians; the skull and teeth are most like those of Dinosaurs; the pelvis and limbs might belong to either Dinosaurs or Crocodiles; while the free astragalus is certainly a Crocodilian character; provisionally it is referred to the Theropodous Dinosauria, and named *Ornithosuchus Woodwardi*.

"The Organogeny of *Asterina gibbosa*." By E. W. MacBride. Communicated by Adam Sedgwick, F.R.S.

"On Copper Electrolysis *in Vacuo*." By William Gannon.

"Note on the Action of Copper Sulphate and Sulphuric Acid on Metallic Copper." By Prof. Arthur Schuster, F.R.S.

Physical Society, December 8.—Prof. A. W. Rücker, F.R.S., President, in the chair.—A paper, by Mr. James Swinburne, on a potentiometer for alternating currents, was read by Mr. Blakesley. After referring to the many advantages of the "potentiometer" method of measurement, the author describes an arrangement by which alternating pressures can be measured. A quadrant electrometer with a double fishtail-shaped needle suspended by a torsionless fibre is employed. The electrostatic attraction exerted by an alternating pressure between the needle and one pair of quadrants is balanced by the force due to a steady pressure between the needle and the other pair of quadrants. The magnitude of the steady pressure is determined by a potentiometer and standard cell, and the effective value of the alternating pressure thus deduced. For measuring alternating currents a differential electrodynamometer having two fixed coils and one moving coil, and no controlling spring, is used. A direct current, measured by the fall of potential over a small resistance, is passed through one of the fixed coils, the alternating current through the other fixed coil, and the moving coil is included in both alternating and direct current circuits. When the two forces balance, the currents are taken as equal. Several small inaccuracies to which the method is subject are mentioned in the paper. Prof. S. P. Thompson inquired if the fishtail-shaped needle of the electrometer was novel. Mr. Blakesley said the author had mentioned the needle previously. He (Mr. Blakesley) thought the name "potentiometer" was not very suitable. In effect, the so-called measurement of *pressures* was a comparison of two *powers*.—The President announced that Mr. Preece's note on the specific resistance of sea-water had been temporarily withdrawn.—Prof. G. M. Minchin made a communication on the calculation of the coefficient of self-induction of a circular current of given aperture and cross-section. Instead of assuming the cross-section of the wire small, and the current density constant over the section, as is usually done, the author takes into account the dimensions of the section and the non-uniform distribution of the current. Making use of the expressions for the vector potential (G) of the current given in his previous papers (*Phil. Mag.* April and August, 1893), the author calculates the total normal flux of force through a surface intersected once in the positive direction by every tube of force emanating from the given current. This flux, divided by the current, gives the coefficient of self-induction. The surface chosen is the circular aperture of the current and half of the anchor ring formed by the wire. When the current density is inversely proportional to the distance from the axis of the circular current, the value of the coefficient of self-induction is found to be

$$\pi\left\{4a(L-2)+2c\left(L-\frac{5}{4}\right)-\frac{c^2}{16a}(2L+19)\right\},$$

where a is the radius of the central filament of the current, c the radius of the cross-section of the wire, and $Le=\log\frac{8a}{c}$. Clerk-Maxwell's approximate expression agrees with this in the principal term. As an example of the closeness of the approximation, the case of a current in a wire 2 millimetres diameter bent to a circle of 2 centimetres mean diameter had been taken, the approximate and corrected coefficients being 58·866 and 59·207 absolute units respectively. When the current in the wire is superficial, as in case of alternating currents of high frequency, the coefficient is somewhat greater, being given by the expression

$$\pi\left\{4a(L-2)+2c\left(L+\frac{3}{2}\right)+\frac{c^2}{16a}(4L+11)\right\}.$$

Incidentally it was pointed out that the function Gx where G is the vector potential at a point distance x from the axis of a circular current was the same as Stoke's *current function* in hydrodynamics. Another paper, on the magnetic field of a current running in a cylindrical coil, was read by Prof. Minchin. The cylindrical coil is regarded as a series of equal circles lying close together and forming a cylindrical surface. Replacing each circular current by its equivalent magnetic shell, the problem of finding the magnetic potential at a point resolves itself into calculating the gravitational potential due to two circular plates of attracting matter, one positive and the other negative, situated respectively at opposite ends of the cylinder. The magnetic potential due to one plate is then deduced in terms of elliptic integrals of the first, second, and third kinds. The President had pointed out that the expressions given in the printed proof of the paper, only applied when the perpendicular from the point to the plate fell within the circle; the author had therefore modified the formula so as to be true generally. From this formula the equipotential curves can be constructed. The same system of curves serve for the plate at the other end of the cylinder by changing the signs of the numerals representing the potentials and giving the curves a motion of translation equal to the length of the cylinder in the direction of its axis. The equipotential curves for the coil can then be deduced by drawing through the points of intersection of the two sets of curves whose numerical values have a constant sum. In determining the curves the author had to calculate tables of elliptic integrals of the third kind, and these he hoped to complete before the paper was published. In reply to a question on the first paper, which had been brought before him by Prof. Perry, the author said that as the diameter of the wire diminished indefinitely, both the self-induction and resistance became infinite, but the ratio L/R became zero. It was interesting to examine what relation betwen the aperture and cross-section gave minimum impedance. If the ordinary expression for it be taken the problem was impossible, but the corrected form admitted of a solution. Prof. Perry hoped the work Prof. Minchin had done so well for circles and cylinders would be extended to cylindrical coils of rectangular cross-section. It was most important to be able to find the shape of the field produced by such coils. Prof. S. P. Thompson inquired if there was any way of deducing the expression for the magnetic force at a point other than that given in the paper on the magnetic field of a circular current (*Phil. Mag.* April, 1893). In reply Prof. Minchin explained how the formula followed at once from the fundamental theorem that magnetic force is the curl of the vector potential. This was based on Laplace's expression for the force between a magnetic pole and an element of current which had been proved experimentally.

Zoological Society, December 5.—W. T. Blanford, F.R.S., Vice-President, in the chair.—The secretary read a report on the additions that had been made to the Society's menagerie during the month of November. Among these special attention was called to a Cunning Bassaris (*Bassaris astuta*), obtained by purchase, to two Jerboas presented by Capt. R. A. Ogilby, and to a fine adult female of the Caucasian Wild Goat (*Capra caucasica*), presented by H. H. P. Deasy.—Prof. G. B. Howes exhibited and made remarks on some specimens of abnormal Marsipobranch Fishes. These were two heads of the Lamprey with the first pair of gills only imperfectly developed, and a Hag (*Myxine glutinosa*) with a supernumerary gill on one side.—Mr. F. E. Beddard, F.R.S., gave an account of the general geographical distribution of Earthworms, as treated of in a work on the subject which he had in preparation. Mr. Beddard recognised sixty-nine genera of this order, divided into six families; and after some preliminary remarks on the artificial introduction of earthworms into districts colonised from Europe, called attention to a series of tables in which the genera found in the six generally recognised regions of the earth's surface were shown. In addition to these six regions Mr. Beddard was disposed to recognise, in the case of earthworms, the existence of an Antarctic region, to embrace New Zealand and most of the Antarctic Islands.—A communication was read from Mr. C. J. Gahan, containing an account of a collection of Coleoptera sent by Mr. H. H. Johnston, C.B., from British Central Africa. Amongst these were examples of eight species new to science.—A communication was read from Capt. F. W. Hutton, F.R.S., containing a report on a collection of Petrels from the Kermadec Islands. Amongst them was an example of a new species proposed to be called *Œstrelata leucophrys*.—Mr. G. A. Boulenger gave an account of *Vipera renardi*, a newly recognised European Viper from Southern Russia and Turkestan.

Entomological Society, December 6.—Henry John Elwes, President, in the chair.—Mr. W. F. Kirby exhibited, for Dr. Livett, specimens of a moth taken at Wells, which Dr. Livett considered to be varieties of *Dasycampa rubiginea*, but which many entomologists present thought were varieties of *Cerastis vaccinii*. Mr. Kirby stated that specimens similar in appearance

to those exhibited had been taken rather freely during the past autumn in Berkshire, and it was suggested that they might be hybrids between *D. rubiginea* and *C. vaccinii.*—Mr. Lovell-Keays exhibited a series of *Lycæna alexis*, with confluent spots on the under sides of the front wings. He drew attention to the fact that the insects were all taken within a short radius, and probably were in the ratio of about one in forty with reference to the ordinary form. All the examples, with one exception, were females. Mr. Lovell-Keays remarked that he had some years ago met with a similar brood near Weymouth, in which the confluent spots were entirely confined to females. Prof. S. H. Scudder, of Cambridge, Mass., U.S.A., stated that he had observed the occurrence of broods of allied species with suffused spots in America.—Mr. C. O. Waterhouse exhibited the type specimen of *Coptomia opalina* of Gory, from the Hope Collection at Oxford, and pointed out that it was quite distinct from *C. mutabilis*, W. Mr. Waterhouse also called attention to *Silpha atomaria* of Linnæus (Syst. Nat., ed. xii., i., p. 574), a Swedish species which appeared to have escaped notice, and was not included in any catalogue. The type is still extant in the Linnean cabinet, and he said he was of opinion that it was *Olibrus geminus* of our collections, but he had not had an opportunity of making a critical examination. He also exhibited male and female specimens of a *Helopeltis* (the Tea-Bug), which he considered a distinct species, occurring only in Assam.—Mr. M. Jacoby exhibited certain species and varieties of the genus *Ceroglossus* from Chili, and Dr. D. Sharp, Mr. J. J. Walker, and Mr. Champion made remarks on their geographical distribution.—Prof. Scudder exhibited the type specimen of a fossil butterfly, *Prodryas persephone*, found in beds of Tertiary Age at Florissant, Colorado. He said the species belonged to the *Nymphalidæ*, and the specimen was remarkable as being in more perfect condition than any of those from the European Tertiaries. He also stated that he had found a bed near the White River on the borders of Utah, in which insects were even more abundant than in the Florissant beds. Dr. Sharp, Mr. Kirby, Mr. H. Goss, and the President took part in the discussion which ensued.—Mr. Goss exhibited hybernating larvæ of *Spilothyrus alceæ*, which had been sent to him by Mr. F. Bromilow from St. Maurice, Nice. Mr. W. F. H. Blandford read a paper entitled "The Rhynchophorous Coleoptera of Japan." The President, Dr. Sharp. Mr. Champion, Mr. McLachlan, and Mr. J. J. Walker took part in the discussion which ensued concerning the distribution of the group and the admixture of Palæarctic and Oriental forms. —Mr. G. T. Bethune-Baker read a paper entitled "Notes on some Lepidoptera received from the neighbourhood of Alexandria," and exhibited the specimens described. Mr. McLachlan suggested that the scarcity of insects in Egypt was possibly to be accounted for by the fact that much of the country was under water for a considerable portion of the year; and Dr. Sharp said that another cause of the scarcity was the cultivation of every available piece of land for centuries past.—Mr. C. O. Waterhouse read a paper entitled "Further Observations on the Tea-Bugs (*Helopeltis*) of India."—Dr. F. A. Dixey communicated a paper entitled "On the Phylogeny of the *Pierinæ*, as illustrated by their wing-markings and geographical distribution."

Geological Society, December 6.—W. H. Hudleston, F.R.S., President, in the chair. The following communications were read:—The Purbeck beds of the Vale of Wardour, by the Rev. W. R. Andrews and Mr. A. J. Jukes-Browne. The authors have obtained better evidence than previously existed for calculating the thicknesses of the several parts of the Purbeck series in the Vale of Wardour, and compared the different subdivisions as developed in that vale with those exposed in other localities. The average thickness of the Lower Purbeck strata was given as 70 feet, of the Middle Purbeck beds about 32 feet, and of Upper Purbeck strata at least 66 feet. A comparison was instituted between the Purbeck beds of the Vale of Wardour and those of the Dorset coast, &c., and some remarks were made upon the physical conditions under which the beds were deposited A discussion followed, in which the President, Prof. J. F. Blake, Prof. T. Rupert Jones, and Mr. H. B. Woodward took part. The Rev. W. R. Andrews briefly replied.—On a picrite and other associated rocks at Barnton, near Edinburgh, by Mr. Horace W. Monckton. The object of this paper was to describe a cutting on a new railway in Barnton Park, where there is an excellent exposure of picrite. It consists of serpentinised olivine, augite, mica, iron oxide, and a little plagioclase-felspar, with a variable amount of insterstitial matter. In many respects it comes very near to the picrite of Inchcolm, which island is 4½ miles north of Barnton cutting It differs from the picrite of Bathgate, and the probability is that the Barnton rock is an offshoot from the same magma as that which supplied the Inchcolm rock. Besides the picrite other igneous rocks from the same cutting were described—in particular, a rock with porphyritic crystals of a green mineral replacing olivine, or more probably augite, and a great quantity of brown mica in small flakes and crystals. It was suggested that the name of mica-porphyrite might be given to this rock. Sir James Maitland made some remarks upon the paper.—On a variety of *Ammonites* (*Stephanoceras*) *subarmatus*, young, from the Upper Lias of Whitby, by the same author. The author described an ammonite found by himself in 1874 near Sandsend, three miles north-west of Whitby. He thought it was not actually *in situ*, but lying with a number of nodules on the floor of an old alum-pit, although he had no doubt that it was from the alum shale of the Upper Lias. A peculiar arrangement of the costæ as they cross the siphonal area distinguishes the specimen from other Whitby ammonites known to the author. It bears a strong resemblance to a shell figured as *A. subarmatus* by D'Orbigny ("Terr. Jurass." pl. lxxvii.), but is unlike the figures of that species given by other authors.

Linnean Society, December 7.—Prof. Stewart, President, in the chair.—Mr. C. T. Druery exhibited and made remarks upon a new example of apospory in *Scolopendrium vulgare*, and Prof. Bower brought forward a similar case in *Trichomanes Kaulfussii*. Mr. George Brebner exhibited some new and rare British Algæ, including *Haplospora globosa*, *Tilopteris Mertensii*, *Ectocarpus tomentosoides*, and *Polysiphonia spinulosa* var. *major*. Mr. F. Enoch, with the aid of the oxyhydrogen lantern, exhibited the various stages of development of the black currant mite, *Phytoptus ribis*, and gave an interesting account of its life history.—Mr. Thomas Christy exhibited a gigantic reed-like leaf from the Zambesi, with drawings of sections. It appeared to be allied to *Sansevieria cylindrica*, but differed conspicuously in the greater size of the leaves, which measured about 9 feet in length, instead of from 18 inches to 3 feet. The remarkably tough and strong fibre which it produces is considered to be of great commercial value, being equal to the best Sansevieria hemp.—Mr. W. F. Kirby read a paper on the dragon-flies of Ceylon, with descriptions of some new species. The paper was based chiefly upon a collection made by Colonel Yerbury, which he had presented to the British Museum. Seventy-five species were enumerated, of which fifty-five had been collected by Colonel Yerbury. Another collection, made in Ceylon by Mr. E. Green, had been dealt with in a previous paper (*Proc. Zool. Soc.* 1891, pp. 203-206).—On behalf of Signor Martelli, the secretary read a paper on the cause of the fall of the corolla in *Verbascum*, which gave rise to an interesting discussion. The meeting adjourned to December 21.

PARIS.

Academy of Sciences, December 11.—M. de Lacaze-Duthiers in the chair.—On the sublimation of the red and yellow iodides of mercury, by M. Berthelot.—Research on the structure of feathers, by M. C. Sappey.—The densities of saturated vapours, and their relation to the laws of condensation and vaporisation of the solvents, by M. F. M. Raoult.—On the burning of moor and forest lands in Gironde, and the exceptional drought during the spring and summer of this year, by MM. G. Rayet and G. Clavel. The long drought of the spring and summer of this year has favoured the production and extension of fires in the pine woods of the department of Gironde. In the 184 days between March 1 and September 1, 132 fires happened in the woods of Gironde, destroying 35,589 hectares of forest land, and doing damage to the extent of six million francs. Similar disasters occurred in 1870, and they have led the authors to look up the rainfall observations for the last 122 years for purposes of comparison. Among other points brought out by the investigation is that only two springs, 1716 and 1768, were drier than that of 1893. The summer of this year, however, only ranked thirteenth in order of dryness. —Solar observations made during the second and third quarters of 1893, by Prof. Tacchini (see Our Astronomical Column).—On the surfaces of which the lines of curvature of a system are plane and equal, by R. T. Caronnet.—On the characters of convergence of series, by M. Hadamard.—Low wave-length

spectrum of fluorine, by M. G. Carvallo.—On the diurnal variation of pressure on the summit of Mont Blanc, by M. A. Angot.—On the transformation of iron, by M. G. Charpy. Osmond's investigations of the transformations of iron led him to conclude that this metal exists in two allotropic forms, α and β, having very different mechanical properties, and, according to him, it is to the transformation of α into β that we must attribute the greater part of the modification undergone by steel during the process of tempering. M. Charpy has investigated the matter, and he finds that permanent deformation by cooling produces in iron and steel of different qualities an allotropic modification of iron. This transformation can be shown by means of curves of extension-tests. In the case of annealed iron and steel the curve showing the stress and strain has a step in it which does not appear when other varieties are tested. The curves thus furnish a simple method of studying the transformation of iron, its influence on mechanical properties, and its *rôle* in tempering.—On the velocities of etherification of hydrofluoric acid, by M. M. Meslans.—Analysis of butters, by M. C. Viollette.—On the buccal armature and a new digestive gland of Cirripedes, by M. A. Gruvel.—On the localisation of the active principles in resedas, by M. L. Guignard.—On the olivine of Maillargues, near Allanche (Cantal), by M. F. Gonnard.—Eruption of the Calbuco volcano, by M. A. E. Nogués (see Notes).—On *Benettites Morierei*, a fossil fruit presenting a new type of gymnosperm inflorescence, by M. O. Lignier.—Employment of artificial cultures of pathogenic microbes in the destruction of troublesome rodents, by M. J. Dampz.

Amsterdam.

Royal Academy of Sciences, November 25.—Prof. van de Sande Bakhuyzen in the chair.—Prof. J. A. C. Oudemans read a paper on the accuracy of the divisions of the altazimuth made by Pistor and Martin, and that by Repsold, for the triangulation of Java. In Pistor and Martin's circles, divided into 5′, the intervals were alternatively larger and smaller in one instance, the difference in an instrument constructed in 1856 being almost $= 6''$; in the other instruments it was much smaller. In Repsold's circles, divided into 4′, no difference was found. The discovery of this imperfection led to a severe examination of all the circles, and the result was that, taking into account this difference, and measuring the intervals of seven degrees of each circle from three to five times, it was found that Pistor and Martin's divisions had grown better and better, so that *within one degree*, the mean error of each line, in the instruments of 1865 and 1867, in linear measure, was only $\frac{1}{9}\mu = \frac{1}{230000}$ of an inch. Two altazimuths of Repsold gave $\frac{1}{22}\mu = \frac{1}{550000}$ of an inch. Account was taken of the errors in the measurement of the intervals by the micrometers of the microscopes. The periodic and irregular errors were, of course, larger.—Prof. Zaaijer read a paper on the sutura condylo squamosa of the occipital bone of man and mammalia. For the first time in 1878 attention was directed to this suture (only part of which remained, and that very rarely, with man) by Dr. W. Dominicus who had found this anomaly on some skulls in the collection of the Anatomical Museum at Leyden. However, this observation remained buried in the dissertation of Dr. Dominicus ("Ontleed kundige aanteekeningen betreffende het achterhoofdsbeen." Leiden, 1878). Last winter Prof. Zaaijer quite accidentally lighted on a human skull (from a grave on the island Disko, Greenland) of which the above-mentioned suture was not obliterated. This induced him to examine the state of the sutura condylo-squamosa of mammalia. By the kindness of the Director of the Museum of Natural History at Leyden, about 1900 skulls of mammalia were examined. The chief result of the examination of the skulls of full-grown animals indicated that the suture was found in its entire state with Marsupialia in 8·6 per cent. of the examined skulls (35 in number), Rodentia 3·9 per cent. (155), Pachydermata 16·5 per cent. (85), Ruminantia 10·5 per cent. (210), Simiæ 1 per cent. (202). With the skulls of the adult animals from the other classes the suture was never found in its entire state, no more than with man. Before communicating these results Prof. Zaaijer gave a short description of the normal development of the occipital bone in man. A minute and close investigation of a great number of human skulls raises the question as to whether the entire obliteration of this suture may not be found more frequently with the so-called lower races.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Dynamos, Alternators, and Transformers: G. Kapp (Biggs).—Electric Traction on Railways and Tramways: A. Reckenzaun (Biggs).—Portative Electricity: J. T. Niblett (Biggs).—The Design of Alternate-Current Transformers: R. W. Weekes (Biggs).—Electrical Distribution, its Theory and Practice, Part 1, M. H. Kilgour; Part 2, H. Swan and C. H. W. Biggs (Biggs).—Town Councillor's Hand-book to Electric Lighting: N. S. Russell (Biggs).—First Principles of Electrical Engineering, new edition: C. H. W. Biggs (Biggs).—Descriptive Catalogue of the Anatomical and Pathological Specimens in the Museum of the Royal College of Surgeons of Edinburgh, Vol. 1, the Skeleton and Organs of Motion: C. W. Cathcart (Edinburgh, Thin).—Romance of the Insect World: L. N. Badenoch (Macmillan).—Elementary Lessons in Steam Machinery and the Marine Steam Engine, new edition: J. Langmaid and H. Gaisford (Macmillan).—A Text-book of the Physiological Chemistry of the Animal Body, Vol. 2, the Physiological Chemistry of Design: Dr. A. Gamgee (Macmillan).—Meteorology: H. N. Dickson (Methuen).—Le Cuivre: P. Weiss (Paris, Baillière).—Key to Lock's Shilling Arithmetic: H. Carr (Macmillan).—About Orchids: F. Boyle (Chapman and Hall).—Annals of British Geology, 1892: J. F. CONTENTS.

THURSDAY, DECEMBER 28, 1893.

QUATERNIONS AS AN INSTRUMENT IN PHYSICAL RESEARCH.

Utility of Quaternions in Physics. By A. McAulay, M.A. (London: Macmillan and Co., 1893.)

JUST as "one shove of the bayonet" was truly said to be more effective than any number of learned discussions on the art of war:—this really practical work, giving genuine quaternion solutions of new problems as well as largely extended developments of old ones, is of incomparably greater interest and usefulness than the recently renewed, but necessarily futile, attempts to *prove* that a unit vector cannot possibly be a quadrantal versor:—nay, that a Calculus of Vectors must limit itself to the beggarly elements of addition and subtraction, commonly called "composition."

It is much to be regretted that Mr. McAulay has not determined simply to let his Essay speak for itself. His Preface, though extremely interesting as the perfervid outburst of an enthusiast, assumes here and there a character of undignified querulousness or of dark insinuation, which is not calculated to win sympathy. It has too much of the "Rends-toi, coquin" to make willing converts; and in some passages it runs a-muck at Institutions, Customs and Dignities. Nothing seems safe. It is a study in monochrome:—the lights dazzlingly vivid, and the shades dark as Erebus! We gladly pass rom it to the main contents of the book.

There can be no doubt whatever of its value from the scientific point of view. It is the work of a man of genuine power and originality. Many parts of it are, no doubt, laboured and somewhat heavy, others very crude; and in some places the obscurity is almost repulsive. [Curiously, these obscurities occur chiefly where more than usual pains have been taken to make things plain!] But faults like these are well-nigh inevitable in a first effort; and they should, perhaps, be regarded as enhancing by contrast the merits of the novel processes and results to which they act as a foil.

It is positively exhilarating to dip into the pages of a book like this after toiling through the arid wastes presented to us as wholesome pasture in the writings of Prof. Willard Gibbs, Dr. Oliver Heaviside, and others of a similar complexion. Here, at last, we exclaim, is a man who has caught the full spirit of the Quaternion system:—"the real *œstus*, the *awen* of the Welsh bards, the *divinus afflatus* that transports the poet beyond the limits of sublunary things"! No doubt, to a man like this, the restrictions imposed, in view of the prospective ordeal of the Senate-House, by the passionless worldly-wisdom of a "Coach," must have been gall and bitterness. Intuitively recognising its power, he snatches up the magnificent weapon which Hamilton tenders to all, and at once dashes off to the jungle on the quest of big game. Others, more cautious or perhaps more captious, meanwhile sit pondering gravely on the fancied imperfections of the arm; and endeavour to convince a bewildered public (if they cannot convince themselves) that, like the Highlander's musket, it requires to be treated to a brand-new stock, lock, and barrel, *of their own devising*, before it can be safely regarded as fit for service. "Non *his* juventas orta parentibus . . ." What could be looked for from the pupils of a School like that?

Mr. McAulay himself has introduced one or two rather startling innovations. But, unlike the would-be patchers or underpinners to whom we have referred, he retains intact all the exquisitely-designed Hamiltonian machinery, while sedulously oiling it, and here and there substituting a rolling for a sliding contact, or introducing a *lignum vitæ* bearing. To borrow an analogy from current electricity, he endeavours to add facilities, while his concurrents are busy adding resistances, sometimes indeed breaking the circuit altogether!

Among the additions to which Mr. McAulay calls attention, some are certainly not novel, they were perfectly well known to Hamilton himself. Thus the use of suffixes, to show which factor of a product (say) is to be acted on by an operator, is at least as old as Herschel's *Appendix* to the translation of Lacroix:—and is an essential part of the notation required for what is correctly called "Hamilton's Theorem." Mr. McAulay refers to this as a process of his own, which was found "necessary somewhat to expand the meaning" of a symbol. Another instance is the use of a vector, *which may have an infinite number of values*, for the purpose of condensing three independent scalar equations into one common expression, &c. This is purely and entirely Hamiltonian.

The "startling innovations," however, as we called them above, are unquestionably Mr. McAulay's own—and he has certainly gone far to justify their introduction. He has employed the sure tests of ready applicability and extreme utility, and these have been well borne. Objections based upon mere unwontedness or even awkwardness of appearance must of course yield when such important advantages as these (if they be otherwise unattainable) are secured; but it certainly requires a considerable mental wrench to accustom ourselves to the use of

$$X_1 \frac{d}{dx_1}$$

as an equivalent for the familiar expression

$$\frac{dX}{dx}.$$

If this be conceded, however, it is virtually *all* that Mr. McAulay demands of us, and we are free to adopt his system. It is to be carefully observed that there is no interference with the *principles* of quaternions to which, as was remarked above, Mr. McAulay strictly adheres. The quantities and operators, to which the dislocation applies, *are all scalars*, and the wrench referred to is therefore an algebraic, not a specially quaternion, one. Its introduction is made necessary by the determination to adhere to the non-commutative property of quaternion multiplication, while endeavouring to effect certain desirable transformations. Mr. McAulay likens this dislocation of the usual arrangement of operator and subject to the occasional disarrangement of relative position of adjective and substantive in a Latin sentence:—the nexus between them being the common case-ending, which is the analogue of the common suffix. A single example,

of a very simple character, must suffice. Thus in the strain of a homogeneous isotropic solid, due to external potential u, we have for the strain-function ϕ (when there are no molecular couples) the equation

$$S.\nabla\phi\alpha + S\alpha\nabla u = 0,$$

which (in virtue of the property of α, already spoken of) is equivalent to three independent scalar conditions. Suppose we wish to express these, without the α, in the form of one vector condition. Mr. McAulay boldly writes the first term as

$$S.\alpha\phi_1'\nabla_1 \text{ ; or rather as } S.\alpha\phi\nabla,$$

for in so simple a case the suffixes are not required, and the strain-function is self-conjugate under the restriction above. Then, at once, the property of α shows us that

$$\phi\nabla + \nabla u = 0,$$

which is the vector equation required. Here it is obvious that, in the usual order of writing,

$$\phi\nabla = \frac{d}{dx}\phi i + \frac{d}{dy}\phi j + \frac{d}{dz}\phi k.$$

This simple example shows the *nature* of the gain which Mr. McAulay's method secures. Those who wish to know its *extent* must read the work itself. They will soon be introduced to novel forms of concentrated operators with regard to which, as I have not yet formed a very definite opinion, I shall content myself by hazarding the remark that, while they are certainly powerful and eminently useful, they must at present be regarded as singularly uncouth.

As a purely personal matter I would add that I do not think Mr. McAulay states quite accurately the nature of some of the remarks which I made on his Essay when I read it (at the request of Dr. Ferrers) in MS. The passage of the last edition of my book, to which he refers as being aimed at him, was meant as a defence or explanation of my own procedure. So far as I can recollect, I urged Mr. McAulay to avoid (when possible) dealing with quaternion *elements*; and to frame relations between surface and volume integrals, &c., from kinematical or other interpretations of their *wholes*.

P. G. TAIT.

THE MANUFACTURE OF PAINTER'S COLOURS AND VARNISHES.

Painter's Colours, Oils, and Varnishes: a Practical Manual. By George H. Hurst, F.C.S. (London: C. Griffin and Co., 1892.)

THIS work is intended for those who are more immediately interested in the manufacture of painter's colours and varnishes; and the author, as he says in his preface, has in the treatment of his subject endeavoured to combine theory and practice by giving a short account of the theory of the processes which he describes. Considering the range of the work and the great number of subjects dealt with, the information thus afforded is necessarily here and there somewhat scanty, and hardly sufficient to work upon. At the same time it appears to us that the bulk of the book might with advantage have been reduced by leaving out most of the elementary chemistry, with which nowadays we must suppose anyone would be thoroughly familiar, who intended to embark on colour-making. A colour-maker ought, above all things, to be a thorough chemist if he wishes to succeed; and those who merely rely on the working of their stock of receipts, secret processes, and rule-of-thumb directions, will have but little chance of success in the future. The author, in his desire to make his work as complete as possible, has also given undue space to the description of numerous colours and processes which are now obsolete, and to others which attracted only a transient interest when issued from the Patent Office.

The uninitiated reader will therefore find it somewhat difficult to separate the chaff from the grain, as it is not always clear whether, in the description of the processes and the properties of the colours obtained by them, the author gives his own experience, or merely a transcript of the patent specification or the trade circular. This criticism applies more especially to the chapter on white pigments. Here it is also to be regretted that the author has not give more prominence to the description of the qualities of the typical whiteleads obtained by the different processes, and has not brought them into comparison with other similar lead compounds, and with the various zinc pigments which have been introduced as substitutes for the poisonous whitelead. The results of such comparative trials carried out systematically, and according to the methods mentioned in the book, would have been of great value, as they would also assign the proper value to those compounds which are so persistently recommended as being equal, or even superior, to genuine old-fashioned whitelead.

With regard to zincwhite, it appears to us that the real reason of its not being more generally employed is not its supposed want of covering power, for well-prepared Belgian zincwhite ground in oil is hardly inferior in this respect to whitelead, but that it does not work so smoothly and freely under the brush, however finely it may be ground. On this account the workman will always prefer to use whitelead, and he will only use zincwhite when he is compelled to do so. We notice that the author, in describing the preparation of zincwhite, says "the vapour of zinc burns, and vapour of zincoxide is emitted in large volumes"; and further on he speaks of the use of "zinc ores, such as calamine and zincblende, and any product of zinc which, being heated in a retort, can be reduced to the metal." Both these statements are absurdly incorrect. Here also we notice that the author, in referring to certain furnace operations, makes frequent use of the term "calcining," but quite indiscriminately, whether the operation is carried out on an open hearth, or in a muffle with the exclusion of air, or in a covered crucible. It is desirable that writers on technical matters should preserve the strict meaning of such terms as this, which have a distinct and specific signification.

The chapter on Barytes the author introduces with the following words:—"Barytes is one of the most important white pigments at the disposal of the painter, probably in this respect ranking next to whitelead." We have no hesitation in saying that this will surprise those who have any acquaintance with the behaviour of barytes when ground in oil or in varnish. It is true that this substance, as shown in the numerous analyses given in this book, enters largely into the composition of a good many commercial colours; but we venture to say

that, with a few exceptions, where the precipitated barium sulphate is used as a basis or bearer of certain colouring matters, the admixture of ground native barytes has no other object than that of adulteration. As an oil paint it is absolutely worthless. But while we have not a good word to say for ground native barytes, especially when it enters into the composition of oil colours, it is quite otherwise with the precipitated or artificial barium sulphate, which, in our opinion, receives here too scanty a treatment, judging by the little the author says about its preparation. It seems almost as if he had quite overlooked its vast importance. He omits to mention that this pigment is principally made from native barium carbonate, or Witherite, by what apparently is a very simple process; a process, however, which only in the hands of very few makers furnishes it in that perfect condition in which it finds so large an application in preparing the surface of paper for chromo-lithography. It is not, indeed, too much to say that this art largely owes its modern development to the introduction and use of this form of barium sulphate. Passing on to gypsum, we think, from the description given, the reader will receive quite an exaggerated idea of the qualities and importance of this substance in its application as a pigment. The author says "its body is not as good as that of white-lead, but it is at least equal to barytes in this respect, and is superior to zincwhite." He also states that it mixes well with either water or oil, and it can be mixed with all other pigments without affecting them. Here we might ask, are these the results of the author's own trials? In speaking of its being used very largely by paper-stainers and makers of paper-hangings, he says it is preferred to barytes on account of its having more body when used for that class of work; "bulk," perhaps, would be a more correct term in this case. We almost suspect that the author, whilst speaking of the use of gypsum as a pigment, really means "satin-white," a substance of some importance to the paperstainer and maker of paper-hangings, which is obtained by precipitating aluminium sulphate with caustic lime, and which is a mixture of calcium sulphate and alumina hydrate. This substance, however, we do not find mentioned in the book before us.

It deserves to be noticed that, according to the author, gypsum as well as barytes and China clay are used in the finishing of cotton goods. We were under the impression that this nefarious and stupid practice had been given up before now. Strontium sulphate, under the name of strontian white, finds also a place amongst the white pigments, and considering the price of strontium minerals, we are not a little surprised to see it stated that strontium sulphate is often sent out as a substitute for barytes. Concluding with the white pigments, we find a very full and interesting account of China clay, and the mode of obtaining it from the natural deposits.

Regarding the article on Vermilion, it appears to us that the author is under an entire misapprehension as to the merits of the dry and wet methods of its preparation. It is incorrect to say that the Chinese product is finer and more brilliant in tone than that made in Europe. The vermilion made at present in Europe by the sublimation process is quite equal to, if not better than, the Chinese; but, as regards colour and fineness, the wet-process vermilion is far superior to either, and is superseding the former.

We should have thought it hardly worth while to mention that the chromates of mercury and silver had been proposed as red pigments, and still less the chromate of copper, which, according to the author, is a dark red (?) coloured body. Under chrome-green we notice that the author takes "Guignet's green" to be chromic oxide, whilst it really is a hydrate of chromium oxide, and the chemical formula he gives for its formation is, of course, quite wrong.

In the article on Ultramarine we notice misspellings of the names of authors, and R. Hoffmann, for instance, is throughout referred to as "Hofmann."

The foregoing remarks have already taken up so much space, that we cannot find room for our comments on the remaining chapters dealing with the colours, and we must conclude here, but not without calling attention to the latter part of the book, which treats of paint vehicles, oils, resins and varnishes, and gives a very full and interesting account of these materials. The description of the manufacture of oil varnishes is particularly valuable, as it gives an exact account of processes which are usually guarded with much secrecy.

BRITISH FUNGUS FLORA.

British Fungus Flora; a Classified Text-book of Mycology. By George Massee. Vols II. and III. (London: Geo. Bell and Sons, 1893.)

IT was originally estimated that this work would be completed in three volumes, but, as we pointed out in our first notice, this was practically impossible. A notice now accompanies the third volume, to the effect that a supplementary volume will speedily be published in conclusion of the work. The second volume continues the Hymenomycetes, which occupy 268 pages also of the third volume, so that two and a half volumes are occupied by the Hymenomycetes, leaving 220 pages for the Hyphomycetes, which bring the third volume to a close. It is only necessary to enumerate the remaining orders to appreciate the difficulty of completing even with a fourth volume. There are all the Ascomycetes, which occupied in Cooke's "Handbook" an equal number of pages to the Hymenomycetes; and supposing the increase to have been in the same ratio, it may be conjectured that this order (including the Discomycetes) cannot be compressed into less than two volumes. For all that remains afterwards, there will not be so much necessity. There would be the *Sphæropsideæ* and *Melanconieæ*, which are of minor interest, although numbering perhaps 700 species. The *Phycomyceteæ*, which have recently been the subject of a volume, by the same author, as "British Fungi, Phycomycetes, and Ustilagineæ." Hence they may be dispensed with. The *Uredineæ*, which, with the *Ustilagineæ*, formed a volume by C. B. Plowright in 1889, have had so few accessions that a revision is not imperative. The *Myxomycetes*, which occupied a monograph by G. Massee in 1892, is all-sufficient. As to the *Saccharomycetes* and the *Schizomycetes*, the little volume by W. B. Grove, dated 1884, would furnish an introduction, and would be fairly

complete to that date, in genera and species. With these modifications, we see no reason why, with two supplementary volumes to contain all the *Ascomycetes*, the five volumes might not be accepted as a fair approximation to a "British Fungus Flora."

As far as the *Basidiomycetes* are concerned, and these will occupy half the bulk of the volumes, even if extended to five, it will be conceded that they are of the greatest interest to the largest number of persons, and, moreover, that they are treated with all the fulness that such an important section demands. We cannot help regretting, however, whenever we are called upon to use the book, that the sequence of families and genera were inverted. The ample descriptions, under each species, will nevertheless atone for much, and justify the appropriation of half the volumes to their service.

The 220 pages which are devoted to the *Hyphomycetes* (or moulds), will be especially welcome to students of microscopical fungi, not only because they are arranged according to the most recent system—that proposed by Saccardo—but also on account of the very useful figures illustrative of the several genera. In our opinion, these are the most successful of the illustrations yet included in the present work. It would have been a great achievement, had it been possible, so to have increased the number of these little outline figures, as to have included every one of the species included in the Flora. As to substantial accuracy, that must, to a large extent, be accepted on trust, since the practical use can be the only test of the merits of the text-book, and its demerits —if any.

We can now estimate the number of British species, and see how they are provided for in this Flora, or may hereafter be included, viz.:—

Gastromycetes	78	... Vol. I.	
Hymenomycetes	1950	... Vols, I. II. III.	
Hyphomycetes	635	... Vol. III.	
			2663
Pyrenomycetes	900		
Discomycetes	610		
Hysteriacei	30		
Tuberaceæ	30		
			1570
Sphæropsideæ, &c.	700		
Uredineæ and Ustilagineæ ...	257		
Phycomycetes	100		
Myxomycetes	100		
Saccharomycetes and Schizomycetes	133		
			1290
Total			5523

The above estimates of the Ascomycetes, at 1570, are only approximate, and probably below, rather than above, the actual number. Hence therefore the total contents of the four or five volumes, as the case may be, would not be less than 4200 species, and the absolute total of all British recorded Fungi upwards of 5500 species, as compared with the 2809 of Cooke's "Handbook" in 1871, or a duplication in twenty-two years. This fact is a sufficient justification for the publication of the present work.

We need not repeat our general commendation, as expressed in our first notice, except perhaps to intimate that in all respects the second and third volumes are up to the level of the first, and justify the confidence reposed by the publishers, and ourselves, in the author to whom such an important work has been entrusted. It would be folly to pretend that it is absolutely perfect, but the errors of judgment, or execution, are not such as to detract from the general utility of the most pretentious and important work which Mr. Massee has yet attempted.

M. C. COOKE.

OUR BOOK SHELF.

Some Salient Points in the Science of the Earth. By Sir J. William Dawson, F.R.S. Pp. 499, with 46 illustrations. 8vo. (London: Hodder and Stoughton.)

THIS volume will have a melancholy interest, especially for the older geologists; for the author says that it "is intended as a closing deliverance on some of the more important questions of geology, on the part of a veteran worker, conversant in his younger days with those giants of the last generation, who, in the heroic age of geological science, piled up the mountains on which it is now the privilege of their successors to stand." We must bear in mind this implied limitation, that the heroic age of geology is now past, and must treat the volume before us as containing an account of researches and speculations made during the lifetime of a bygone generation. It is, in fact, a sort of scientific autobiography, touched up here and there to agree with recent research, but not claiming authority as an epitome of the present state of our knowledge.

Few chapters in the history of geology are so fascinating as Lyell's account of the discovery, by Principal Dawson and himself, of the wonderful series of remains from the coal field of Nova Scotia. It reads like the story of the exploration of a new country. We seem to walk among the strange vegetation of the coal; we see the larger reptiles crawling over and leaving trails in the soft mud; and on the dry land we help to pull to pieces one of the hollow trees, and find within it a number of land animals, all new to science. We can understand how these discoveries came as a complete surprise to the scientific world in days when few or no reptiles were known of earlier date than the Permian, and no land mollusca earlier than the Eocene. The reader will naturally turn first to the chapters relating to the researches in the coal measures, and it is probably on the observations there recorded that the author's fame will principally rest. Sir William Dawson's exploration of the coal measures of Nova Scotia led him to devote particular attention to the natural history of that period. He studied carefully the physical conditions under which the strata were laid down, devoting special attention to the formation of underclays and to the origin of coal seams; he still stands up for the dry-soil origin of coal, and for its growth on the spot. From the origin of coal it was a natural transition to the coal-measure plants, and these the author has worked at most industriously, though the present volume only contains a summary of his researches. There is also a chapter on the air-breathers of the coal, in which the author gives an account of his explorations at South Joggins.

We do not much care for the chapters on the genesis and migrations of plants, on the distribution of animals and plants as related to geographical and geological changes, and on Alpine and Arctic plants in connection with geological history. In all such subjects the author's strong bias against evolution in any form leads him to use strange arguments. We do not wish, however, to conclude this notice with a criticism of minor points, and though unprepared altogether to praise Sir William Dawson's volume, we thoroughly recognise how much he has done for the science of geology, and we gladly welcome in this handy form a short record of his life's work.

Das Karstphänomen. Versuch einer morphologischen monographie von Dr. Jovan Cvijić. (Wien: Ed. Hölzel.)

NOTWITHSTANDING its rather pompous second title, this is an interesting and valuable book, which, however, is not a separate work, but the third part of the fifth volume of a geographical series (*Abhandlungen*) edited by Prof. A. Penck. Its subject may be briefly stated as follows:—In many limestone districts the surface of the rock is guttered by channels—sometimes small, sometimes large—varying from comparatively smooth to rough. Here each ends in a small pipe, which descends vertically into the rock; there they converge towards one of larger size. With this system of superficial drainage are associated hollows of various forms, "blind valleys," and the like, and caves are likely to be common. A region which exhibits some or all of these phenomena is called, from the peculiar sculpture of the surface, a *karst* region. Such may be found in various parts of the world. It is represented in England by the furrowed limestones and "swallow-holes" of Derbyshire and Yorkshire; it occurs in many parts of the Alps, the phenomena becoming more frequent eastward, till their headquarters are reached in the Julian Alps and the great "Karst plateau," north of the Gulf of Fiume. As they occur in many lands, so they bear many names. A full, exhaustive, and elaborate account of these interesting phenomena will be found in this memoir, perhaps with an affected attempt at precision in distinction and classification (for after all, though curious, they are simple in origin), together with abundant references to the literature of the subject. Its usefulness, however, would be greatly increased by an index or by a very full table of contents; and though it is paged continuously with the volume, the latter, at least, ought to have been given.

T. G. B.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Origin of Lake Basins.

THE most thorough-going glacialist could find no ground for complaint that Dr. Wallace has not gone far enough in his most interesting advocacy of the glacial origin of lakes. I do not propose to enter into any general discussion of this question; that glaciers can excavate rock basins is indisputable, but there is a limit to their power, and this limit I believe to be reached far short of even the larger of our English lakes. The controversy is of long standing, and there is little new to be said on either side; nor would I have desired to re-enter it, but that Dr. Wallace's article seems to me to contain one serious fallacy and one vital misstatement which have not as yet been noticed, though they should not be left uncorrected.

The fallacy is not a new one; it may be found in the writings of more than one of the advocates of the glacial theory, and is contained in the argument that because lakes are found in regions that have been extensively glaciated, and are not found in regions precisely similar in every respect, except that there has been no great extension of glaciers, therefore the rock basins in which the lakes lie were excavated by glaciers. I trust I have not misrepresented the argument in this succinct statement of it; but such condensation is useful if we would detect a fallacy, and in this condensed form the fallacy of the undistributed middle term becomes conspicuous. The term "lake" is by no means coextensive with the term "rock basin," and it is not the water filling the lake which requires explanation so much as the basin that it fills. A rock basin filled with alluvium is a rock basin still, and requires explanation as much as if it contained water, and was consequently a lake.

The misrepresentation is to be found in Dr. Wallace's limitation of what he rightly regards as the only tenable alternative theory, that the rock basins owe their origin to deformation of the surface immediately before the advance of the ice. This limitation of time is so extraordinary that it would have passed for an accident or oversight, but that it is repeated at greater length on the very next page; did it form any essential part of the theory, this would deserve all the strictures passed upon it, but such is by no means the case. Without entering into the question of whether the geologists quoted by Dr. Wallace accept this limitation of time, I may point out that it is altogether more reasonable to regard the deformation as having taken place *after* the advance of the glaciers. We know that during the glacial period there were great changes of level, and it is reasonable to suppose that these were not absolutely uniform; moreover, had the rock basins been formed before the ice was there to fill them, they would mostly have been filled at once by river deposits, as has been the case in nonglaciated regions, and once filled up they would remain so on this theory, for if a glacier cannot erode a rock basin it cannot clean out one that has been filled up with stream deposits. This alteration of time makes the theory more natural and acceptable; when a rock basin is formed in the course of a stream by elevation or subsidence no lake arises in the great majority of cases, as either the barrier is destroyed by corrasion, or the hollow is filled up by deposition, as fast as it is formed; but when the basin arises underneath a glacier it becomes occupied by ice, and on the retreat and disappearance of the glacier a hollow is left that is at first filled by water, forming a lake, and only subsequently by degrees filled up by stream deposits. In this way the connection between the present distribution of lakes and the areas of pleistocene glaciation is easily explicable, and it is consequently not admissible as an argument to prove that the lake basins were excavated by glaciers until it is shown that in the nonglaciated regions, where there are now no lakes, there are also no rock basins.

With most of the regions quoted by Dr. Wallace I have no personal acquaintance, but in India such do certainly occur, and have as certainly not originated by glacial erosion; in some cases the existence of the rock basin has been proved by borings, but besides these there are many more instances where there can be no reasonable doubt of the existence of a rock basin, though the final test has not been made.

R. D. OLDHAM.

IN his last communication Sir Henry Howorth makes two statements which are so erroneous and so misleading that I cannot allow them to pass without correction. The first is, that Mr. Deeley "repudiates Dr. Wallace's notion that regelation can in some way act as a compensating element when crushing supervenes in ice." Here is a double misstatement. Mr. Deeley "repudiated" no notion of mine, or he would, I am sure, have said so plainly, and he said nothing whatever about "crushing." Neither did I say a word about regelation acting as a "compensating element," for I do not believe in the crushing of glaciers by their own pressure. I asked Sir Henry what would happen to the ice after it was crushed, the pressure continuing; and I get no reply but the above double misstatement.

Then, further on, Sir Henry says: "Mr. Wallace confesses he does not like to face these mechanical issues." This is simply untrue. I "confessed" nothing of the kind, and I challenge Sir Henry Howorth to quote any words of mine which will bear such a meaning. I maintain that his "mechanical issues" are pure theories, and are beside the question of the actual facts of glacier notion. Lastly, he attempts to evade the real issue between us, which is, that he himself accepted Charpentier's conclusions as to the extent of the Rhone glacier, but refuses to allow me to use these same conclusions as a datum in the discussion.

I have now shown ample reason why further discussion of this matter with Sir Henry Howorth must be unprofitable.

ALFRED R. WALLACE.

The Second Law of Thermodynamics.

I AM unable to see any reason for regarding Clausius' supposed deduction of the Second Law as in any way limited by the condition stated by Mr. Burbury, viz. "that the system be conservative, that is, that the external as well as the internal forces acting on it are to be derived from a potential." No such limitation was contemplated by me when I was preparing the Report for the British Association.

It is true that this assumption is made in § 17 of the Report, in order to establish the closest possible connection between the

deduction and Hamilton's Principle of Least Action. But the limitation is required by the postulate, viz. the Principle of Least Action, not by the deduction. Clausius expressly states (*Phil. Mag.* vol. xliv. (1872) p. 365) that his deduction holds good for systems to which the Principle of Least Action is not directly applicable, and in consequence he claims that his equations involve a new principle which is of more general application than Hamilton's Principle (*vide* Report, § 16). I think there can be little doubt that Clausius had in his mind the very objection which Mr. Burbury now raises, and that it was in order to meet it that he claimed this generalisation.

The assumption as to the conservative nature of the forces is not required except in § 17 of the Report, and at the end of that paragraph two methods of avoiding it are suggested. One is to assume that the force-function can be varied with the time, the other is a method adopted by Von Helmholtz.

If we allow the force-function to be varied with the time, then in Mr. Burbury's case (of a column of gas held down by a piston of constant mass) the potential of *gravity* can be altered and therefore the *weight* of the piston is disposable. This disposes of Mr. Burbury's objection, and it only remains to consider the investigations given at the beginning of § 17 of the Report.

Clearly the Second Law of Thermodynamics cannot be deduced from studying the behaviour of gas under constant pressure. To establish it we must make the working substance undergo a reversible cycle in which heat is absorbed and external work performed. To do this we attach the piston to a crank as in an ordinary steam engine, and make it turn a wheel which raises a weight by means of a windlass. Here we have a strictly conservative system, and one to which the arguments of § 17 are therefore strictly applicable. And for every single turn of the wheel we have

$$\int \frac{dQ}{T} = O \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

a relation identical in form with that which expresses the Second Law.

It seems to me that the real objections to Clausius' deductions are far more intricate and far less easily disposed of. The difficulty of assigning a physical meaning to the quasi-period i is one of them, and there are other difficulties connected with the interpretation of T as absolute temperature when intermolecular forces are taken into account. All these difficulties are alluded to in my Report, and they are not peculiar to the hypothesis of "quasi-periodic" motions; similar difficulties exist in some form or other in most so-called "proofs of the Second Law."

It may be interesting to mention that a proof of the Second Law based on the virial equation

$$pv = \tfrac{2}{3}(T + \Sigma\Sigma(\tfrac{1}{2}Rr))$$

was given by R. C. Nichols in the *Philosophical Magazine* for 1876 (v. Series I. p. 369). I hope later on to deal more fully with that portion of Mr. Burbury's letter which relates to the "virial proof."

G. H. BRYAN.

December 21.

Flame.

I HAD hoped that after disavowing the unpleasant interpretation which had been put upon his first letter, Dr. Armstrong would have done me the honour, and himself the justice, of indicating precisely where he disagreed with my scientific arguments. Instead of doing so, he has imputed to me a sensitiveness to criticism so excessive that he feels it best to retire from the controversy with a mere statement that our standpoints are different. I must leave it to the readers of NATURE to judge whether Dr. Armstrong has any longer the right to claim a *standpoint*.

Mr. Newth will find a fuller discussion of my views about flame in the *Journal of the Chemical Society* for 1892, pp. 204–226. If after reading that he still has difficulty in understanding the fundamental points of my work, I shall be glad to help him if he will communicate with me privately. With a little care, Mr. Newth will find it quite easy to separate the two cones of a carbon monoxide-air flame in the ordinary apparatus without the use of a gauze cap. The air must be turned on very gradually. In the case of the hydrogen-air flame it is best to dilute the gases with nitrogen, as recommended in my first paper.

I am sorry that anyone should think I have slighted Dr. Frankland's work. I can, however, understand, and even admire, Mr. Newth's excessive zeal in the matter.

ARTHUR SMITHELLS.

"The Zoological Record."

WE are delighted to find such a consensus of opinion as to the desirability of retaining palæozoology in the *Zoological Record*. The recorders whom we have consulted, the editor, and now the secretary of the Zoological Society, all have expressed themselves in its favour. The question therefore is purely one of finance. Under these circumstances the publication of the correspondence with the Geological Society is of great interest, and the only addition that we could suggest would be the publication in your columns of that poverty-stricken society's balance-sheet.

We should like, however, to point out that the *Zoological Record* appeals to the Geological Society, not merely on the ground of its palæontological contents. Palæontologists go to the *Record* to learn what the neontologists are doing, quite as much as to read the titles of their own papers. Under any circumstances, then, the *Zoological Record* has some claim on the Geological Society, and we must all regret that financial distress prevents the Society from acknowledging that claim.

But the Record Committee of the Zoological Society need not despair; for the *Record* has no less claims on many other of our learned societies, and, by the converse argument, the inclusion of palæozoology merely strengthens those claims. Every biologist should be grateful to those who bring to his notice literature that he would otherwise never hear of. Apart from this, one-third of the volume is devoted to entomology. Why should the Entomological Society not be invited to contribute? Then there are the Royal and the Linnean Societies, and the British Association; the Microscopical, we would mention, did it not already do excellent work of a similar kind. At any rate, surely five of these bodies could be prevailed on to subscribe £20, or even £40 a-piece. The Zoological Society appeals through its *Record* to hundreds of workers who do not belong to it. It has long done an admirable work, of which it will never lose the credit. Everyone should sympathise with it in its present attempt to perfect this work, and should not permit it to suffer so large a pecuniary loss in that attempt.

December 17.

R. I. POCOCK.
F. A. BATHER.

On the Bugonia-Superstition of the Ancients.

LAST August, I published in the *Bulletin Soc. Entomol. Italiana*, 1893, p. 186-217, an article entitled "On the Bugonia of the Ancients, and its relation to *Eristalis tenax*, a two-winged insect." I desire to collect some more materials on that subject, in view of a second edition, and I would be very grateful to readers of NATURE who may be able to give me assistance in that matter.

The information I require may be expressed in two questions:

(1) Whether travellers in out-of-the-way places in Europe or Asia have not come across vestiges of the superstition about oxen-born bees, still lingering among primitive people?

(2) Whether readers of Oriental literature have not come across passages evidently referring to this superstition, like the passage I reproduce here as an example. I found it in the "Golden Meadows" of the Arab traveller Massoudi (died in Cairo, 955), translated by Barbier de Meynard and Pavet de Courteille, Paris, 1861, vol. iii. p. 233. It relates a conversation which took place in Arabia, and of which this is a fragment. "'Had the bees, which produced this honey, deposited it in the body of a large animal,' asked Yiad? The surveyor answered: 'Hearing that there was a hive near the sea-coast, I sent people to gather the honey. They told me that they found at that place a heap of bones, more or less rotten, in the cavity of which bees had deposited the honey that they brought with them.'"

I have sent separate copies of my paper to the Geographical, Linnean, and Entomological Societies in London, to the Natural History Museum, South Kensington, to the Athenæum Club, and to many friends in England. I should be happy to send a copy to anybody interested in the subject.

C. R. OSTEN SACKEN.

The Earliest Mention of the Kangaroo in Literature.

I TAKE advantage of the present opportunity to put another question to zoologists. In the same book of Massoudi, whom I quoted in the previous notice, I found the following passage (vol. i. p. 387):—"El Djahiz, in his 'Book on Animals,' relates that the female rhinoceros is pregnant for seven years,

during which the cub protrudes the head from the belly of the mother, in order to browse, and withdraws it afterwards. Desirous of being better informed, I asked the people of Siraf and Oman, who visited this country, as well as merchants whom I had met in India. They all told me that the rhinoceros breeds just like the cow and the buffalo; and I do not know where El Djahiz has found this story, whether among his reading, or from his inquiries." This is evidently an obscure tradition about the Australian kangaroo, which had reached some part of Asia, and was connected with the rhinoceros by people who knew nothing about either of the two animals. Has the attention of zoologists been called to this story before?

Heidelberg, Germany, December 5. C. R. Osten Sacken.

On an Undescribed Rudimentary Organ in Human Attire.

Lecturers who are tired of the cockade hat-ribbon and tail buttons, may be glad to know of the following rudiment. The old-fashioned double eye-glass was a folder, with a knob at the outer side of the distal glass; and this on folding locked against a pin on the outer side of the proximal glass. The double eye-glass of the present day does not fold; but, none the less, is the knob outside the distal glass retained for it, though there is no pin to lock with on the proximal glass. How long will it take before this useless rudiment disappears? What will be the cause of its disappearance? As panmixia is out of the question, we may prophesy that it will be economy of material.

Cork, December 12. Marcus Hartog.

EARLY ASTERISMS.[1]

III.

The Constellations referred to in the Myth of Marduk and Tiāmat.

We are indebted to the myth, then, for the knowledge that when it was invented the constellations Bull, Scorpion, Goat, and Fishes had been established.

This argument is strengthened by the following considerations suggested by Jansen:—

"We look in vain among the retinue of Tiāmat for an animal corresponding to the constellations of the zodiac to the east of the vernal equinox. This cannot be accidental. If therefore we contended that the cosmogonic legends of the Babylonians stood in close relationship to the phenomena of sunrise on the one hand and the entrance of the sun into the vernal equinox on the other; that, in fact, the creation legends in general reflect these events, there could not be a more convincing proof of our view than the fact just mentioned. The three monsters of Tiāmat, which *Marduk* overcomes, are located in the 'water-region' of the Heavens, which the Spring Sun *Marduk* 'overcomes' before entering the (ancient) Bull. If, as cannot be doubted, the signs of the zodiac are to be regarded as symbols, and especially if a monster like the goat-fish, whose form it is difficult to recognise in the corresponding constellation, can only be regarded as a symbol, then we may assume without hesitation that at the time when the Scorpion, the Goat-Fish, and the Fish were located as signs of the zodiac in the water-region of the sky, they already played their parts as the animals of Tiāmat in the creation legends. Of course they were not taken out of a complete story and placed in the sky, but conceptions of a more general kind gave the first occasion. It does not follow that all the ancient myths now known to us must have been available, but certainly the root-stock of them, perhaps in the form of unsystematic and unconnected single stories and concepts."

There is still further evidence for the constellation of the Scorpion.

Jensen remarks:—

[1] Continued rom vol. xlviii. p. 520.

"A Scorpion-Man plays also another part in the cosmology of the Babylonians. The Scorpion-Man and his wife guard the gate leading to the Māšu mountain(s), and watch the sun at rising and setting. Their upper part reaches to the sky, and their *irtu* (breast?) to the lower regions (Epic of Gistubar 60,9). After Gistubar has traversed the Māsu Mountain, he reaches the sea. This sea lies in the east or south-east. However obscure these conceptions may be, and however they may render a general idea impossible, one thing is clear, that the Scorpion-Men are to be imagined at the boundary between land and sea, upper and lower world, and in such a way that the upper or human portion belongs to the upper region, and the lower, the Scorpion body, to the lower. Hence the Scorpion-Man represents the boundary between light and darkness, between the firm land and the water region of the world. *Marduk*, the god of light and vanquisher of Tiāmat, *i.e.* the ocean, has for a symbol the Bull = Taurus, into which he entered in spring. This leads almost necessarily to the supposition that both the Bull and the Scorpion were located in the Heavens at a time when the sun had its vernal equinox in Taurus and its antumnal equinox in Scorpio, and that in their principal parts or most conspicuous star groups; hence probably in the vicinity of Aldebaran and Antares, or at an epoch when the principal parts of Taurus and Scorpio appeared before the sun at the equinoxes."

If my suggestion be admitted that the Babylonians dealt not with the daily fight but with the yearly fight between light and darkness—that is, the antithesis between day and night was expanded into the antithesis between the summer and winter halves of the year; then it is clear that at the vernal equinox Scorpio setting in the west would be watching the sunrise; at the autumnal equinox rising in the east, it would be watching the sunset; one part would be visible in the sky, one below the horizon in the celestial waters. If this be so all obscurity disappears, and we have merely a very beautiful statement of a fact, from which we learn that the time to which the fact applied was about 3000 B.C., if the sun were then near the Pleiades.

Jensen in the above-quoted passages by implication, and in a subsequent one directly, suggests that not all the zodiacal constellations were established at the same time. The Babylonians apparently began with the easier problem of having six constellations instead of twelve. For instance, we have already found that to complete the present number, between

Scorpio. Capricornus. Pisces.

we must interpolate

Sagittarius. Aquarius.

Aries and Libra seem also to be late additions according to Jensen, who writes:—

"We have already above (p. 90), attempted to explain the striking phenomenon that the Bull and Pegasus, both with half bodies only, ἡμίτομοι, enclose the Ram between them, by the assumption that the latter was interposed later on, when the sun at the time of the vernal equinox stood in the hind parts of the Bull, so that this point was no longer sufficiently marked in the sky. Another matter susceptible of a like explanation may be noted in the region of the sky opposite to the Ram and the Bull. Although we cannot doubt the existence of an eastern balance, still, as already remarked (p. 68), the Greeks have often called it χηλαὶ 'claws' (of the Scorpion), and according to what has been said above (p. 312), the sign for a constellation in the neighbourhood of our Libra reads in the Arsacid inscription 'claw(s)' of the Scorpion. These facts are very simply explained on the supposition that the Scorpion originally extended into the region of the Balance, and that originally α and β Libræ represented the 'horns'

of the Scorpion, but later on, when the autumnal equinox coincided with them, the term Balance was applied to them. Although this was used as an additional name, it was only natural that the old term should still be used as an equivalent. But it also indicates the great age of a portion of the zodiac."

Let us suppose that what happened in the case of Aries and Libra happened with six constellations out of the twelve, *in other words, that the original zodiac consisted only of six constellations*. We should have—

Taurus	Crab (or Tortoise)	Virgin (or ear of corn)	Scorpion	Capricornus	Pisces
Gemini	*Lion*	*Libra*	*Sagittarius*	*Aquarius*	*Aries*

The upper list not only classifies in an unbroken manner the Fish-Man, the Goat-Fish, the Scorpion-Man, and Marduk of the Babylonians, but we pick up all or nearly all of the ecliptic stars or constellations met with in early Egyptian mythology, Apis, the Tortoise,[1] Min, Selk, Chnemu as represented by appropriate symbols.

Further, the remarkable suppression or small representation of the Lion in both the more ancient Babylonian and Egyptian mythology is explained. I have shown before how the Babylonians with an equinoctial year would take slight account of the solstice, while it also follows that the Egyptians, who were wise enough not to use zodiacal stars for their warnings of sunrise for the reason that stars in the brighter light of dawn near the sun are more difficult to see, might easily neglect the constellation of the Lion as first Phact and then Sirius, both southern stars, marked for them the advent of the summer solstice; on different grounds, then the Lion might well have been at first omitted in both countries.

Since there is a doubt as to the existence of the Lion among the first Babylonian constellations,[2] the argument in the following paragraph would appear to refer to observations made at a later time when totemism was less prevalent :—

"The Lion in the heavens must represent the heat of the summer. He does this most effectually when the summer solstice coincides with the constellation, that is, when its principal stars appear before the sun at the summer solstice. This happened at the time when the vernal equinox lay in Taurus, and when the principal star-group of the Bull appeared before the sun at the time of the vernal equinox. The water-jug (Amphora)—Aquarius must represent symbolically the watery season of winter. It does this most effectually when the winter solstice coincides with it, or its principal star-group appears before the sun at the winter solstice. This happened about the time when the vernal equinox lay in Taurus, and its principal star-group rose before the sun at the time of the vernal equinox."

The above suggested basis of the Babylonian mythology, regarding the demons of Tiāmat, established when the sun was in Taurus at the spring equinox, enables us to understand clearly the much later (though similar) imagery employed when the sun at the equinox had passed from Taurus to Aries—when the Zend Avesta was written, and after the twelve zodiacal constellations had been established. We find them divided equally into the kingdoms of Ormuzd and Ahriman. Here I quote Dupuis :[1]

"L'agneau est aux portes de l'empire du bien et de la lumière, et la balance à celles du mal et des ténèbres ; l'un est le premier des signes supérieurs, et l'autre des signes inférieurs.

"Les six signes supérieurs comprennent les six mille de Dieu, et les six signes inférieurs les six mille du diable. Le bonheur de l'homme dure sous les premiers signes, et son malheur commence au septième, et dure sous les six signes affectés à Ahriman, ou au chef des ténèbres.

"Sous les six signes du règne du bien et de la lumière qui sont agneau, taureau, gémaux, cancer, lion et vierge ou épi nous avons marqué les états variés de l'air et de la terre, qui sont le résultat de l'action du bon principe. Ainsi on lit sous l'agneau ou sous le premier mille ces mots, printemps, zephyr, verdure ; sous le taureau, sève et fleur ; sous les gémeaux, chaleurs et longs jours ; sous le cancer, été, beaux temps ; sous le lion, épis et moissons ; et sous la vierge, vendages.

"On passant à la balance, on trouve les fruits ; là commence le règne du mal aussitôt que l'homme vient à cueiller les pommes. La nature quitte sa parure ; aussi nous avons écrit ces mots. Dépouillement de la nature, sous le scorpion on lit froid ; sous le sagittaire, neiges ; sous le capricorne, glace et brouillard, siége des ténèbres et de long nuits ; sous le verseau, pluies et frimas ; sous les poissons, vents impétueux."

We now return for a moment to Ia.

Associated with Ia was an Ia-star, which Jensen concludes may be η Argûs. This we must consider.

Jensen concluded that the Ia-star is η Argûs, on the ground that many of the texts suggest a darkening of it now and again ; he next proceeds to point out that a variability in the star is the only point worth considering in this connection, and by this argument he is driven to η, which is one of the most striking variables in the heavens, outshining Canopus at its maximum. Speaking generally, everybody would agree that observation by clouds, &c., would not be recorded, but if the star were observed just rising above the southern horizon only, then its absence, due to such causes, would, I should fancy, be chronicled, and it must not be forgotten that this is precisely the place where it would be observed, for in the first place it was to the south of the heavens, what Bil was to the north, and the temple sacred to it at Babylon was oriented to the south.

But η Argûs never rose or set anywhere near the south. I have ascertained that its declination was approximately $33\frac{1}{2}^\circ$ S. in 6000 B.C., and increased to 40° S. by about 2000 B.C. Hence between these dates at Eridu its amplitude varied between 38° and 47° S. of E. or W. Now here we are far away from the S. point, though very near the S.E. or S.W. point, to which it is stated the Babylonian structures had their sides oriented.

The question arises whether there was a star which answers the other conditions. There was a series of such stars. First, beginning with the most recent ; we have *Canopus*. 6000 B.C. its declination was $62\frac{1}{2}^\circ$, it would then have been below the horizon of Eridu, first making its appearance with a declination of 59° nearly at the south point in 4700 B.C. Phact would follow in 5400 B.C. Achenar would make a similar appearance for the first time about 8000 B.C. It may be here mentioned generally that the precessional movement must, after certain intervals, cause this phenomenon to be repeated constantly with one star after another. May this explain the "other animals" who subsequently appeared like Ia (Oannes)? The whole myth is, I think, clearly one relating to men coming (from the south?) to Eridu in ships. The boat is turned into a "fish man," and the

[1] I think I am right about the Tortoise, for I find the following passage in Jensen, p. 65, where he notes the absence of the Crab:—"Ganz absehend davon, ob dasselbe für unsere Frage von Wichtigkeit werden wird oder nicht, muss ich daran erinnern, das unter den Emblemen, welche die sogenannten "Deeds of Sale" häufig begleiten, verschiedene Male wie der Scorpion so die Schildkröte abgebildet gefunden wird. . . ."

[2] Jensen, p. 314.

[1] "Origine des Cultes," vol. vii. p. 82.

star to which they pointed to show whence they came or made a god.[1]

It will have been gathered that the constellations of the Bull and the Scorpion were recognised as such at the same early date both in Babylonia and Egypt, and this of course implies intercommunication.

The ecliptic stars in use in Babylonia in later times are as follows[2]:—

1.	η Piscium.	15.	α Leonis.
2.	β Arietis.	16.	ρ Leonis.
3.	α Arietis.	17.	β Leonis.
4.	η Tauri.	18.	β Virginius.
5.	α Tauri.	19.	γ Virginius.
6.	β Tauri.	20.	α Virginius.
7.	ζ Tauri.	21.	α Liliæ.
8.	η Geminorum.	22.	β Liliæ.
9.	μ Geminorum.	23.	δ Scorpionis.
10.	γ Geminorum.	24.	α Scorpionis.
11.	α Geminorum.	25.	δ Ophiuchi.
12.	β Geminorum.	26.	α Capricornis.
13.	δ Cancri.	27.	γ Capricornis.
14.	ε Leonis.	28.	η Capricornis.

With regard to the complete ecliptic, the information seems meagre both from Babylonia and from Egypt in early times.

As to later times in Babylonia—say 1000 B.C.—the following list represents the results of Jensen's investigations :—

(1) Perhaps Aries (= "leading sheep").
(2) A "Bull (of the Heavens)" = Aldebaran or (and) = our Taurus.
(3) Gemini.
(4) ?
(5) Perhaps Leo.
(6) The constellation of the "corn in ears" = the ear of corn. [Spica.]
(7) Probably Libra, whose stars are, however, at least in general, called "the claw(s)" (*i.e.* of the Scorpion).
(8) The Scorpion.
(9) Perhaps Sagittarius.
(10) The "goat fish" = caper.
(11) ?
(12) The "Fish" with the "Fish band."

In Egypt we find no such sharp references as the above to either the poles or the great circles, but dating from the twentieth dynasty (1100 B.C.), and therefore almost contemporaneous, is a series of star tables which have puzzled Egyptologists from Champollion and Biot downwards.

Looking at them they seem to be observations of stars made during the twelve hours of the night on the 1st and 16th of every month. The chief stars seem to be twenty-four in number, and it looked at first as if we had really here a list of priceless value of twenty-four either ecliptic or equatorial stars.

Unfortunately, however, the list has resisted all efforts to completely understand it. Whether it is a list of risings or meridian passages even is still in dispute. Quite recently, indeed, one of the investigators, Herr Gustav Bilfinger,[3] has not hesitated to consider it not a list of observations at all, but a compilation for a special purpose.

"The star-table is intended to carry the principle of time into the rigid world of the grave, and represents over the sepulchral vault, 'the eternal horizon' as the ancient Egyptians so aptly styled the grave, an imitation of the sky, a compensation for the sky of the upper world with its time-measuring motion ; yet the idea here is bolder, the execution is more artificial and complicated, since the sculptor endeavoured to combine the daily and the annual motion of the celestial vault in *one* picture ; wanted to transfer into the grave the temporal frames in which all human life is enacted. This endeavour to represent by one configuration both motions and both chronological units explains all the peculiarities and imperfections of our star-table.

"The simplest means of representing both motions was found in the stars, which circle the earth in the course of a day and indicate the year by the successive appearance of new stars in the morning twilight. If the same stars were to serve both purposes in one representation, it was necessary to take twenty-four stars which rose at intervals of fifteen days, since only such followed each other at an average distance of 15°, and were therefore useful for showing the hours."

"If the calendar-maker really possessed a list of the twenty-four principal (zodiacal) stars, the course of the year was indicated thereby ; but since he also wanted to represent the daily motion, he might with some justice have composed each night out of eleven of these stars, since the stars' risings are only visible during the ten middle hours of the night. But ten hours would not have adequately represented the night, since this was thought of as a twelve hours' interval.

"There was a way out of it, viz. to call hora 0 'sunset,' hora 12 'sunrise,' which would have been a simple and correct solution if the division of the night into twelve parts for practical purposes had been aimed at. But this expedient he could not adopt, because he could or would only operate with stars, and the notions of sunrise and sunset found no place in his tables. Thus he was forced to *falsify* the customary division of the hours, by squeezing the twelve hours of the night into the time during which star risings are visible, viz. the dark night exclusive of twilight. On the other hand he could not, with his principal stars at intervals of 15°, divide his night, shortened as it was by two hours, into twelve parts, and thus he was obliged to make use of two or three auxiliary stars, as we have proved in detail above, and thus yet more to disfigure the hour-division, since thereby the lengths of the hours were made very variable. These are then two things which we must not regard as peculiarities of ancient Egyptian reckoning, but as a consequence of the leading idea of our table, which did not intend to facilitate the division of the night into twelve parts by star observations, but was calculated by the connection of thirteen stars with thirteen successive moments to create the idea of the circling host of stars and thence the course of the night."

I give an abstract of the list of the twenty-four principal stars and the constellations in which they occur :—

1. Sahu = Orion.
2. Gothis = Sirius.
3. The two stars.
4. The stars of the water.
5. The lion.
6. The many stars.
7. Mena's herald.
8. Mena.
9. Mena's followers.
10.
11.
12. Hippopotamus.
13.
14.
15.
16.
17. Necht.
18.
19.
20.
21. Ari.
22. } Goose.
23. }
24. Sahu = Head of Orion.

It will be seen that this Egyptian star list is very indeterminate, but there are other lists, which are much more definite, represented by the Indian Nakshatras, the Arab Manâzil al-Kamar, and the Chinese Sieu.

Hindu Asterism.	Arab Manzil.	Chinese Sieu.
1. Açvinî (The two gods) β and γ Arietis	1. ash-Sharatân (The two signs) β and γ Arietis	1. Mao η Tauri
2. Bharanî (Carrying away) 35, 39, and 41 Arietis	2. al-Buṭain (The little belly) 35, 39, and 41 Arietis	2. Pi ε Tauri
3. Kṛttikâ (Has been explained as matting ; doubtful) η Tauri, &c. (Pleiades)	3. ath-Thuraiyâ (Probably "the cluster") η Tauri, &c. (Pleiades)	3. Tse λ Orionis
4. Rohinî (Red) α, θ, γ, δ, ε Tauri	4. ad-Dabarân ("The follower" of the Pleiades) α, θ, γ, δ, ε Tauri	4. Tsan δ Orionis
5. Mṛgaçiras (Head of deer) λ, ϕ^1, ϕ^2 Orionis	5. al-Hak'ah (The circle of hairs) λ, ϕ^1, ϕ^2 Orionis	5. Tsing (A well) μ Geminorum
6. Ârdrâ (Damp) α Orionis	6. al-Han'ah (Apparently "the wishing Asterism") η, μ, ν, γ, ξ Geminorum	6. Kuei θ Cancri
7. Punarvasu (Twice bright) β, α Geminorum	7. adh-Dhirâ' (The arm) β, α Geminorum	7. Lieu (The willow) δ Hydræ
8. Pushya (Auspicious) θ, δ, γ Cancri	8. an-Nathrah ("The point between lip and nostrils" of Leo) γ, δ Cancri, and Præsepe	8. Sing (A star) α Hydræ
9. Âçleshâ (Embracing, serpents) ε, δ, σ, η, ρ Hydræ	9. aṭ-Ṭarf ("The eyes" of Leo) ξ Cancri, λ Leonis	9. Chang ν^1 Hydræ
10. Maghâ (The strong ?) α, η, γ, ζ, μ, ε Leonis	10. aj-Jabhah (The forehead) α, η, γ, ζ Leonis	10. Y α Crateris
11. Pûrva Phalgunî (Grey) δ, θ Leonis	11. az-Zubrah (The shoulder) δ, θ Leonis	11. Chin γ Corvi
12. Uttara Phalgunî β, 93 Leonis	12. aṣ-Ṣarfah ("The change" of weather) β Leonis	12. Kio (A horn) α Virginis
13. Hasta (Hard) δ, γ, ε, α, β Corvi	13. al-Auwâ ("The howler," sometimes conceived as a dog barking round Virgo) β, η, γ, δ, ε Virginis	13. Kang (Overbearing, strong) κ Virginis
14. Citrâ (Beautiful) α Virginis	14. as-Simâk (The prop) α Virginis	14. Ti (A foundation) α^2 Libræ
15. Svâtî α Bootis	15. al-Ghafr (Of uncertain sense) ι, κ, λ Virginis	15. Fang (Room, dwelling) π Scorpionis
16. Viçâkhâ (Fork) ι, γ, β, α Libræ	16. az-Zubânân ("The two claws" of the scorpion) α, β Libræ	16. Sin (The heart) σ Scorpionis
17. Anurâdhâ (Blissful) δ, β, π Scorpionis	17. al-Iklîl (The crown) β, δ, π Scorpionis	17. Uei (High) μ^2 Scorpionis
18. Jyeshthâ (The best) α, σ, τ Scorpionis	18. al-Ḳalb (The heart) α Scorpionis	18. Ki γ^2 Sagittarii
19. Mûla (Root) λ, υ, κ, ι, θ, η, ζ, μ, ε Scorpionis	19. ash-Shaulah ("The sting" of the scorpion) λ, υ Scorpionis	19. Teu φ Sagittarii
20. Pûrva-Ashâdhâ (Unconquered) δ, ε Sagittarii	20. an-Na'âim (The ostriches) γ^2, δ, ε, η, φ, σ, τ, ζ Sagittarii	20. Nieu β Capricorni
21. Uttara-Ashâdhâ (Unconquered) σ, ζ Sagittarii	21. al-Baldah (The hairless space between the eyebrows) N of π Sagittarii	21. Nü ε Aquarii
22. Abhijit (Victorious) α, ε, ζ Lyræ	22. Sa'd adh-Dhâbiḥ (Sa'd (luck) the sacrificer) α, β Capricorni	22. Hiü β Aquarii
23. Çravana (Lame) α, β, γ Aquilæ	23. Sa'd Bula' ("Greedy Sa'd," because the larger star seems to swallow the smaller) ε, μ, ν Aquarii	23. Goei α Aquarii
24. Çravishthâ (Most glorious) β, α, γ, δ Delphini	24. Sa'd as-Súûd ("The luck of lucks" = specially lucky star β, ξ Aquarii	24. Che α Pegasi
25. Çatabhishaj (?) λ Aquarii, &c.	25. Sa'd al-Akhbiyah ("Sa'd with the tents") α, γ, ζ, η Aquarii	25. Pi γ Pegasi
26. Pûrva-Bhâdrapadâ (Having ox feet) α, β Pegasi	26. al-Fargh al-Muḳdim (The front lip of the bucket) α, β Pegasi	26. Koei ζ Andromedæ
27. Uttara-Bhâdrapadâ (Having ox feet) γ Pegasi, α Andromedæ	27. al-Fargh al-Mukhir (The hinder lip of the bucket) γ Pegasi, α Andromedæ	27. Leu β Arietis
28. Revatî (The rich) ζ Piscium, &c.	28. Baṭn al-Hût (The fish's belly) β Andromedæ, &c.	28. Oei 35 Arietis

I mention these, because although their dates are uncertain, they are undoubtedly built upon a common model, they have identical functions, and they have to do with the ecliptic, that is to say, we are in each case in presence of a belt of stars to which the motions of any other heavenly body travelling round the sun or, like the planets, round the earth, like the moon can be readily referred. In these lists[1] I give translations of the Sanscrit, Arab, and Chinese names, so far as they can be made out, and I must here express my deep obligations to Profs. Max Müller, Robertson Smith, and Douglas, for their kindness in supplying them.

J. NORMAN LOCKYER.

THE SECONDARY EDUCATION MOVEMENT.

THE outcome of the Oxford Conference on Secondary Education in England is our usual panacea for social ills, a Royal Commission. As this is to be, let us hope that the reference will be restricted to some definite points, and the members to a small number of properly qualified persons. Otherwise little else than unnecessary delay will be the result. Practical experience of such Commissions tends, however, to disenchant one with the prevailing idea of their usefulness, that is, of their power to settle the question at issue. Look at the last Commission on Primary Education, containing bigwigs of every kind. How long they sat, and how many Blue Books they filled with evidence, may be learnt by those who are interested. But what did it all come to? The large majority reported that they were totally opposed to free education, and the small minority, though not opposed, saw no possibility of its accomplishment. Two years afterwards a Tory Government carried a Free Education Act! Again, a Royal Commission on Vaccination has been sitting every Wednesday for the last five years, and it has not yet finished taking evidence! In face of facts like these, and they might be greatly extended, can one look with much hope to the early settlement of so difficult and complex a question as English secondary education by a Royal Commission as usually constituted? There are two conditions under which Commissions of this kind can act usefully: first, as means of inquiry into facts, and such a one was the Technical Commission of 1881–4, which journeyed over sea and land in quest of information; and second, as a means of carrying out measures laid down by Act of Parliament; and such a one, for example, is the Scottish University Commission now sitting. If we do not now know what we want in the way of secondary education, let there be a Commission by all means. Many may think that we do know. We are all convinced that more good secondary schools are needed both in town and country; and what has to be decided are such matters as how these schools are to be governed, by whom new ones are to be set up, and old ones remodelled to suit the wants of the times, how the necessary funds are to be found, and so forth. Now, are these questions of a kind which a Royal Commission can once for all determine? I think not. In my opinion they can only be settled by the House of Commons. The rival claims of County Councils, now in possession of the funds; of School Boards, now entrusted with primary education; of existing public schools of various orders; and, lastly, of private venture schools of all sorts and sizes, cannot be met or satisfied by any report of a Royal Commission. They must be fought out on the floor of the House, and it is by no means clear that the outcome of such a struggle will be in accordance with the recommendations which the report may contain. Therefore, desiring, as all those interested in education must do, to see the present chaos reduced to some degree of order without delay, and the crying needs at least to some extent supplied; and, knowing that there is no present prospect of Government action on such a scale as to systematise our varied forms of educational activity, I, for one, should be satisfied to get a Bill through the House of Commons consisting of two clauses, the first making the educational use of the whisky money compulsory and permanent, and the second giving County Councils power to expend such a portion as they think fit, of the funds capable of devotion to technical instruction, on the furtherance of secondary education. That an expenditure in this direction of some of the money especially voted by Parliament for technical instruction is justified by the acknowledged fact that it is impossible to carry on such instruction, except on the lowest level, to persons ignorant of the educational tools which have to be used.

But, in fact, technical instruction, as defined in the Act, is, or may be, modern secondary education, for it includes all the necessary subjects with the exception of classics and, perhaps, of English and history. So that under these Acts schools—either free or fee'd—can now be established wherever the County Councils determine, and these may be, to all intents and purposes, middle-class secondary schools. Moreover, under these Acts, the local authority may aid existing schools so as to enable them to give scientific or technical instruction. Both of these modes of action are now being widely adopted by County Councils all over the country, so that something substantial in the direction of what is needed is being done. There is, of course, considerable difference of opinion as to the best steps to be taken to bring about a complete and satisfactory system; and for the purpose of ventilating the subject, the Oxford University, in its corporate capacity, took the unprecedented step of calling a conference of the teachers of England, from the university to the elementary school, to discuss the whole question of secondary education. The gathering was remarkable in many ways, but chiefly as an admission, on the part of the universities, of the need of radical educational reform, and of the wisdom of their participation in such reforms. The papers read and the discussions held were, of course, of the multifarious and somewhat discursive order. All, however, from Dean Gregory on the one side, to Mr. Lyulph Stanley on the other, agree "that something should be done," but we may seek in vain for any consensus of opinion as to how that "something" is to be done, or even what that "something" is, except, indeed, the consignment of the matter to the tender mercies of a Royal Commission. Nevertheless, much good may come from the conference; many wise things were said, and the coming together of a large number of persons all in one way or another interested in assisting the progress of the question, cannot be without its useful effect.

What one misses chiefly in the discussion is the scientific aspect of the question. Scarcely a speaker touched upon what, I take it, is after all the gist of the whole matter, viz. the necessity, above all and under all, for an education based upon science. We have to deal, as was well said by Dr. Hewitt, of the Cheshire County Council, not with the 10 per cent. of the population to whom we teach the "humanities," but with the 90 per cent. of humanity struggling for existence. If we want to hold our own with foreign nations, we must alter, and that rapidly, and not waste our precious time too much in inquiry. With the object of raising the standard of existence for these teeming millions the nation now pays £750,000 a year, not enough, perhaps, to accomplish all we require, but amply sufficient for pre-

[1] Reproduced from the Journal of the American Oriental Society, vol. vi. No. II. p. 468, as given by Profs. Whitney and A. H. Newton.

sent use, especially when we remember that County Councils can, if they please, levy a rate in addition to the Imperial grant. We shall agree with Dr. Gull, of the Grocers Company's School, that the battle of scientific and technical training *versus* the humanities ought to be decided by evolution and natural selection, rather than by authority; though what this latter exactly means I do not quite understand. Authority can only act when evolution and natural selection—in other words, public opinion—has decided what is wanted. But we shall disagree with him when he says that "no time could be worse than the present for settling this question." We say that no time can be better, or rather that no time can be so good as the present; for if we do not settle the question soon it will be too late, and our people will lag so far behind those of other countries, that we shall not be able to fetch up our lee way, and the victory will not be to us. To my mind much nonsense is talked, especially by those whom I may without offence call the high-faluting educationists, about so-called culture, and of the necessity for the study of grammar and the humanities for children of every degree. Mr. Bowden, President of the Union of Teachers, is not one of these. He calls attention to the fact—deplorable enough—that only about five per cent. of our five million of children on the registers of elementary schools are in the sixth standard. This being so, it is our duty to give these few children whose parents are willing and able to let them pass on to a higher level of education in secondary schools, that which will most effectively fit them for the life which they afterwards have to follow. Ours is essentially an industrial population, and as the Duke of Devonshire said, at another conference on the same subject, "any advance in the direction of utilising existing secondary schools must be made not for the benefit of the middle classes only, but also of the whole of the working-class community of this country"; and to this I may add Mr. McCarthy's axiom, that school machinery which makes for clerkly employment at the expense of the skilled handicrafts, is so far harmful. Still, it is mainly our middle-class education which is in chaos and needs reform. The higher secondary education is probably sufficiently provided for by over 100 so-called "public" schools having a total of from 26,000 to 27,000 pupils. Primary education is under State direction, and will improve from year to year. To amend the middle-class education is more important even than to improve the educational ladder. Mr. Llewellyn Smith's most excellent report on the condition of secondary education in London shows how crying is the necessity in the metropolis for such middle-class schools. The few that exist in the kingdom are often insufficiently endowed, and their work is generally hampered by competition with private venture schools; and how bad the education is, which is given in many of these middle-class private schools, can, as Dr. Gull says, hardly be conceived. These inefficient schools must be either mended or ended before we can make much progress, and for this we need a Registration of Teachers Act, and an effective system of inspection. Honest private schools would benefit, and the others would disappear.

Of all the communications made concerning the relations present and prospective of the universities to the secondary education of the country, the letters read by Prof. Jebb, from the late Master of Balliol, are of the greatest interest, as giving the latest opinions of one who throughout his life was an educational, and especially a university, reformer. Dr. Jowett stated his desire that there should be a universal abiturienten examination, giving the right of admission to the universities. Then he wished to give all students who pass such an examination the right of becoming candidates, without residence or restriction of age, for any university examination, with or without honours, or for any part of the examination. He further remarks that such persons should have the privilege of admission to the libraries, of competing for university certificates and prizes without restriction of age. Moreover, he would give to such candidates as have shown any considerable merit, sums of money to enable them to carry on their inquiries; and this, says Prof. Jebb, was intended by Dr. Jowett to apply to all branches of knowledge without distinction, which the universities could best teach. These are indeed truly radical proposals, for they mean throwing open the university honours and emoluments to the world. That such measures should have been suggested in the almost dying words of the greatest master of the greatest of Oxford colleges, is in itself remarkable evidence of the present position of Oxford opinion. If fifty, or perhaps twenty, years ago, a radical undergraduate were to have made such suggestions, he would have stood a chance of being expelled from the university, like Shelley, for blasphemy; now they are the last words of Jowett, quoted in the presence of the Vice-Chancellor, with approval by Jebb.

H. E. ROSCOE.

THE SONNBLICK MOUNTAIN OBSERVATORY.

THE progress of meteorological science having rendered necessary a more careful investigation of the conditions of the higher strata of the atmosphere, the subject of mountain stations was considered at the Meteorological Congress at Rome, in 1879, and the various problems which could best be solved by such observations or in balloons were discussed. Among these may be mentioned:—The decrease of temperature with height, especially during cyclones and anticyclones; terrestrial and solar radiation; the behaviour of barometric maxima and minima at the earth's surface and at great heights, and the increase of wind velocity with height. Several important stations were already in existence, and the establishment of others was strongly recommended. Herr Ignaz Rojacher, the proprietor of the Rauris gold mines, having proposed to the Committee of the German and Austrian Alpine Club, in the year 1884, the erection of a meteorological station at the Miners' House on the Sonnblick, in the province of Salzburg, situated at an elevation of 7550 feet, about halfway between Kolm-Saigurn and the summit of the Sonnblick, Dr. Hann, director of the Austrian Meteorological Service, gladly took advantage of the suggestion, and in December of that year the station was equipped by the Austrian Meteorological Institute. But it was soon found that the site was unfavourable for the purpose, and Herr Rojacher decided that the only suitable position would be the summit of the mountain. After surmounting many difficulties, the work was satisfactorily carried out in the early part of 1886. The Alpine Club undertook the expense of the erection of a wooden house, while the Austrian Meteorological Society provided the self-recording instruments and undertook the building of a substantial tower for the anemometer and the establishment of telephonic communication between the summit and Rauris, a distance of 15½ miles, and, further, to supply instruments to the base station at Kolm-Saigurn. The accompanying illustration shows the position of the Observatory on the peak of the mountain; it is situated at a height of about 10,150 feet, and is the highest station in Europe. The difficulties of dragging the materials for the construction of the Observatory over glacier and snow for a distance of about 900 yards can hardly be overrated. Each trip occupied from three to four hours, and it was at this stage of the work that the greatest assistance was given by Herr Rojacher and his men. His intimate knowledge of the conditions of the glacier and *névé*, obtained from thirty-five years' residence in the neighbourhood, enabled him to select a favourable

site and to carry out successfully the construction of the building. Dr. J. M. Pernter has given a graphic description of the difficulties of an ascent which he made in February 1888 (NATURE, vol. xlii. p. 273), during which the foremost guides sank to their hips at every step, despite their use of snowshoes. The maintenance of the station in winter was a matter of great difficulty; but it was materially facilitated by the fact that the Miners' House workmen were at hand for the conveyance of fuel and for carrying out any necessary repairs. But in the year 1888 Rojacher was compelled, from failing health, to sell the mine, and in 1889 operations were discontinued; he succumbed in January, 1891, and then Kolm was abandoned altogether. Under these circumstances, the difficulty of continuing the Sonnblick Observatory was increased. The observer could not remain alone on the summit, separated from all human communication by

a difficult journey of several hours over the snow, and it became necessary to hire men specially to carry up the fuel. The Salzburg section of the Alpine Club gave up the use of the house on the Sonnblick, and their contribution was, to a great extent, withdrawn, so that the maintenance of the Observatory was jeopardised. It was under these conditions that the Sonnblick Society, whose first report for 1892 we received a short time ago, was formed for the purpose of aiding in the expense of continuing this most important station. The Society already numbers 280 members, and, in addition to several other contributions, receives considerable subventions from the Austrian Government and the Committee of the German and Austrian Alpine Club.

Since the establishment of the Observatory in 1886, several valuable discussions on the conditions of the atmosphere in the higher regions have emanated from the pen of Dr. Hann and others, and these have already materially modified the prevalent ideas relative to the nature and origin of storms. In the present report Dr. Hann gives a general account of the climate deduced from observations taken up to the present time. From this it is seen that in each winter the temperature has fallen below minus 22°, and in March, 1890, it fell to minus 30°·3. The warmest month is August with a mean temperature of 33°·6, and the coldest month is February, mean temperature 5°·5. The precipitation is mostly in the form of snow; even in the six summer months, May to October, fully 85 per cent. of the fall consists of snow; out of about 200 wet days in the year, rain only fell on 21 days, and then it was often a kind of sleet. The greatest rainfall measured in one day was 2·8 inches on September 1, 1890. The amount of cloud is perhaps of most importance to tourists; this is most prevalent in June and least in December, just the opposite to what obtains in the lowlands. The month of June has only a quarter of the possible amount of sunshine, while in December it has about half the possible amount. Thunderstorms are less frequent on the Sonnblick than in the lower regions, and generally are not so severe. The Observatory is protected by a properly erected lightning conductor, and contains a room suitable for anyone who may wish to carry on researches at a great altitude. This room is entirely reserved for scientific purposes; another apartment, capable of accommodating twenty persons, has been provided for ordinary visitors. The Sonnblick Society deserves the thanks of all meteorologists for carrying on the work in their Observatory. The establishment of the mountain station has led to the elucidation of many obscure problems, and still more important results can confidently be expected.

NOTES.

MLLE. KLUMPKE, who has just gained the degree of Doctor in Mathematical Sciences at the Sorbonne, is the first lady who has obtained that distinction. The full title of her thesis was "Contribution à l'étude des anneaux de Saturne," and the following is a translation from *La Nature* of the complimentary terms in which M. Darboux addressed the gifted authoress in granting her the degree:—"You have occupied yourself with one of the most interesting questions in astronomy. The great names of Galileo, Huyghens, Cassini, and Laplace, without speaking of those of my illustrious colleagues and friends, are connected with the history of each of the great advances in the attractive but difficult theory of the rings of Saturn. Your work is not a slight contribution to the subject, and it places you in an honourable position among the ladies who have devoted themselves to the study of mathematics. During last century Mlle. Marie Agnesi gave us a work on the differential and integral calculus. Since then Sophia Germain, as remarkable for her literary and philosophic talent as for her mathematical faculties, was held in esteem by the great geometers who honoured our country at the beginning of this century. And but a few years ago the Academy of Sciences, on the report of a commission in which I had the honour to take part, awarded one of its best prizes to Mdme. Kowalewska, placing her name by the side of those of Euler and Lagrange in the history of discoveries relating to the theory of the movement of a solid body around a fixed point. In your turn you have entered upon your career. We know that for some years you have devoted yourself with great zeal and success to investigations connected

with the star-chart. Your thesis, which you have prepared according to our course of higher mathematics, with an assiduity that we could not ignore, is the first that a lady has presented and successfully sustained before our Faculty to obtain the degree of Doctor of Mathematical Sciences. You have worked in a deserving manner, and the Faculty has unanimously decided to declare you worthy of the grade of Doctor."

M. MAREY has accepted the Presidency of the French Photographic Society, in succession to Dr. Janssen, who has retired after completing his full term of office—three years.

THE *British Medical Journal* says that a branch of the Pasteur Institute will be established at Algiers next year.

THE death is announced of Dr. E. Lellmann, Professor of Chemistry at Giessen University.

WE regret to announce that Prof. A. Sprenger, the celebrated orientalist, died on December 19, at the age of seventy-five.

MR. W. L. H. DUCKWORTH has been elected to a Natural Science Fellowship at Jesus College, Cambridge. The new Fellow took a First Class in both parts of the Natural Science Tripos (1892–93), attaining distinction in Human Anatomy and Anthropology, and has published several papers on points connected with these sciences. His election is creditable both to his College and to the rising School of Anthropology which Prof. Macalister has founded in Cambridge.

THE *University Correspondent* says that the late Mr. Alexander Low Bruce, son-in-law of Dr. Livingstone, the explorer, has left £3,000 for the purpose of founding a Chair of Public Health in the University of Edinburgh.

THE Franklin Institute has awarded the following John Scott Legacy Medals and Premiums:—Mr. J. B. Edson, for his invention of a pressure-recording gauge; Mr. N. W. Perry, for his system of series electric traction for railways; Mr. J. T. Wilkin, for a method and apparatus for generating cycloidal surfaces; Mr. W. F. C. Morsell, for an application of polarised light to the systematic study of colour and crystal patterns for design, and Mr. F. Shuman, for his machine and process for embedding wire-netting in glass.

THE report of the Meteorological Council for the year ending March 31, 1893, which has recently been issued, contains an account of the progress in the various discussions in hand. In the branch of ocean meteorology, much valuable information has been added to the current charts for the Atlantic, Pacific, and Indian oceans, from the log-books of H.M. ships, and from data furnished by Foreign Governments. The latter observations are mostly for the Pacific Ocean, where they are comparatively scarce. For another investigation, the district between the Cape of Good Hope and New Zealand, all available data have been dealt with in the construction of monthly charts of the various elements, and the council have decided that the next district to be discussed shall be the South Atlantic. The work in the branch of weather telegraphy and forecasts continues to increase; comparisons of the results of forecasts issued during the hay harvest season, and of those regularly issued at night for the morning newspapers, show respectively a success of 88 and 79 per cent., taking an average of all districts, but for some localities the success was considerably higher. The work included under the climatology of the British Isles is steadily continued, and among the various investigations may be mentioned a discussion of the results of the harmonic analysis of the daily curves for temperature at the observatories, which has been laid before the Royal Society by General R. Strachey, chairman of the council, and of which an abstract is given in the report. Among the miscellaneous subjects we notice a description of a proposed new form of pressure gauge, which is the outcome of the investigations on wind measurements that have been carried out by Mr. W. H. Dines; and, also, that the council have commenced the regular tabulation of the hourly values of sunshine for seven observatories, since the year 1881. The results of an inquiry into fog observations, by Mr. Scott, for the years 1875–90, have been published by the Royal Meteorological Society.

AT the meeting of the French Meterological Society on December 5, M. Angot stated that while investigating the diurnal range of the amount of cloud at Paris, and representing it by a harmonic series, he had found that the semi-diurna period showed a range absolutely opposite to that of the diurnal variation of the barometer, so that the maximum of the semi-diurnal period in the amount of cloud corresponded to the minimum of pressure, and *vice versa*. We agree with M. Angot that it would be interesting to find whether the same relation holds for other places, in which case a proof would be given of the influence of the diurnal variation of the barometer upon the amount of cloud.

A DIFFERENTIAL method of determining the refractive index of solutions to which the interferential refractometer is not adapted, is described by W. Hallwachs in the current number of *Wiedemann's Annalen*. The former instrument is only applicable to measurements of differences of refractive power between very dilute solutions and their solvents. For higher concentrations the prism method has been generally used. But between these degrees of concentration and the former there lies a long series of solutions to which neither method is well suited. For these, Mr. Hallwachs has adopted the following arrangement. A beam of sodium light falls upon a plane-parallel plate of glass at an incidence of nearly a right angle, and is refracted into the glass and out on the other side, thus only skimming the surface on one side. The glass plate divides the solution from the solvent, and stands at right angles to another vertical plane-parallel plate, the two forming a combination in the form of a T. The beam traverses the solution and the second plate, and emergence at an angle with the first plate, which is read by a scale and micrometer. For differences of refractive index of 0·001, 0·005, and 0·1 the angles were in one case 6°, 13°, and 63° respectively, where with a prism of 60° they would only have been 0·15°, 0·8°, and 16°. In practice, the beam was first sent from the medium into the solution, and then from the solution into the medium, thus eliminating any errors in the position of the plates. The difference of refractive index was equal to the square of the sine of the angle of emergence divided by the sum of the two refractive indices. It was found that the molecular refractive index of the substance is decidedly affected by changes in concentration, accompanied by changes of molecular volume, while the specific refractive power of the substances is, curiously enough, very little disturbed. It appears that the effects of dissociation chiefly influence the density.

FOR some weeks there have been appearing in the *Electrician* accounts of devices for compensating the effects of hysteresis of the iron which is used in measuring instruments. The current number of that journal contains a short account, by Messrs. Field and Walker, of some experiments they have made, at Prof. Perry's suggestion, with this object in view. The principle of the method employed is to place a piece of hard magnet steel as a shunt between the poles of the electromagnet used in the instrument. When the magnetised current is passing, some of the lines of force pass through this shunt. When the current is broken, the lines of force in the air gap, due to the residual magnetism in the electromagnet and in the hard steel, will be in opposite directions, and by suitably proportioning the

length and section of the steel, it is possible to arrange that the two residual magnetisms shall just neutralise each others effect in the air gap. A rather novel method was employed to measure the current. A small rectangular tunnel was made in an ebonite plate, placed between the pole-pieces of the electro-magnet, connecting two large flat cylindrical vessels, one of which communicated with an almost horizontal glass tube. Electrodes were fixed on opposite sides of the tunnel, at the part of the field it was required to measure, so that a current could be passed across the tunnel. Under these circumstances, when there was a magnetic field between the pole-pieces, on passing a current between these electrodes and through the mercury, the mercury tended to flow from one of the cylinders to the other. A little alcohol placed above the mercury in the one cylinder flows along the inclined tube, and by its position indicates the pressure exerted by the mercury. The current through the mercury being constant, the pressure is proportional to the strength of the field. The authors say that by the above means it is possible to obtain visible readings for minute variations of the field, whether it be strong or weak.

IN the Proceedings of the Boston Society of Natural History, vol. xxvi. July, 1893, we note that Mr. Warren Upham re-asserts his theory of the formation of drumlins in the neighbourhood of Boston. He now brings forward as confirmatory evidence the occurrence of deflected glacial striæ in Somerville, north-west of Boston. Mr. Upham's theory, which was fully expressed a year ago (Proc. B.S.N.H. vol. xxvi. December, 1892), supposes a rapid accumulation of the drumlins taking place during a period of rapid melting of the ice-sheet. Such periods were episodal occurrences, followed temporarily by re-advance of the ice or cessation of its melting; they mark the oscillatory nature of the influences which brought about the final recession of the ice from these areas. The material forming the drumlins was primarily collected by the ground-ice carried upwards through the ice-sheet as a result of the differential velocities of flow in the superficial and ground-ice. It became, after tracing a steep parabolic curve, part of the super-glacial drift, and began then a slowly descending movement, owing to surface-melting during the retreat of the ice. As the superficial drift was washed onwards and downwards over the melting ice, it was gradually transformed into true till. If now an advance of the ice-sheet took place, the super-glacial and englacial drift would be caught between a more rapidly-moving upper current of ice and a thin lower stratum of slowly-moving ice. The drift would suffer, therefore, from shearing movements, and be gathered into great lenticular masses, or sometimes long ridges, of drumlins, probably farther altered and added to before their final exposure. These are the main arguments of Mr. Upham's theory, to several of which grave objections have already been made by Prof. Davis, Mr. G. H. Barton, and others.

IN *Petermann's Mitteilungen*, November, 1893, a coloured map is published in illustration of Sir Thomas Elder's Australian Expedition of 1891–92. The map is reduced from the original to scale 1 : 3,000,000. The routes of travel, the stations at which the various observations were taken, and the geographical features of the country traversed, are all fully entered. The editor gives a brief statement of the objects of the expedition and its attendant success (pp. 269–270).

A WRITER in "Insect Life" (vol. vi. No. 1.), issued by the U.S. Department of Agriculture, describes a remarkable example of mimicry by a spider. At Jamesburg, N.J., in August of this year, his attention was drawn to what was apparently a gall, perfectly formed, and growing upon the upper surface of a leaf of a small oak tree. On handling the leaf, however, the supposed gall rolled off, and when it was picked up was found to be in reality a spider (*Ordgarius Cornigerus*, Hentz) which had been resting on the leaf, its curiously formed abdomen simulating exactly both in form and colour the common oak gall, even to the tiny punctures through which the gall insect makes its exit when mature.

GUSTAV EISEN has commenced the description of the earthworms of California; though a dry and rainless country for six months in the year, it still would seem to possess a worm fauna rich both in species and individuals. With the exception of two very imperfectly described species by Kinberg, no true earthworms have been recorded from this part of the world. While reserving a detailed account for the Transactions of the Californian Academy, Mr. Eisen gives diagnoses of Deltania, a new genus near Microscolex, with three new species; *D. elegans* (pretty widely diffused, and the largest species of the genus, being from two to four inches in length); *D. troyeri* (from Golden Gate Park, San Francisco); and *D. benhami* (Alameda County). Argilophilus is a new genus near Plutellus; *A. ornatus*, n. sp., is the most common earth-worm of the region, aud *A. papillifer*, n. sp., is a more southern form. (*Zoe* for October, 1893, vol. iv. p. 248.)

THE current number of *Danckelman's Mittheilungen* contains an account of an exploring trip made to the upper regions of Togo, between the years 1890 and 1892, by Captain E. Kling and Dr. R. Büttner. Copious extracts from Captain Kling's diary of his journey are given, with sketches of the features, tattoo marks, and head-dresses of the various tribes of natives he met with; there is also figured a hobby-horse played with by the children, which was made from a strong stalk of millet (in the drawing it looks like a bamboo cane), the head of a horse with ears and bridle being carved out of the root. Very extensive collections of the natural history of the countries visited were made, and astonishingly complete details, considering the time that has elapsed since the specimens were received in Berlin, are given. The lists of the mammals, reptiles, and amphibia of the Togo district are by P. Matschie, the birds of the environs of Bismarckburg are named by Dr. Ant. Reichenow, tbe fish and crustacea by Dr. F. Hilgendorf, the mollusca by Prof. E. Martens, the insects by Drs. H. Stadelmann and F. Karsch and H. J. Kolbe, the worms by A. Collin. The collection of plants has been only in part worked out, about 560 flowering plants species of were found, and a small number of ferns, lichens, and fungi. In a series of thirteen plates made from photographs taken by Dr. R. Büttner, there are views of Bismarckburg, of the natives of Adeli, Bimbila, &c. With investigations like these in addition to those pursued by our own countrymen, the tropical parts of Africa will soon be better known than the northern regions of the continent which lie within the sight of Europe.

THE order of the Laminariaceæ is one of the most distinct and well defined among the Phæosporeæ, the members of this order of sea weeds are all of comparatively large size, while the species of Macrocystis reach a length, even surpassing that of some tropical "climbers," and those of Lessonia possess stems which in appearance resemble the trunks of some trees. Since the date (1848) of J. G. Agardh's "Species Algarum" no attempt has been made to classify the numerous genera of this order, but in a very interesting memoir on the classification and geographical distribution of the Laminariaceæ, by W. A. Setchell, which appears in a recent number of the Transactions of the Connecticut Academy (vol. ix. 1893), we find the order divided into three tribes: I. Laminariideæ, with (1) Laminarieæ, containing the three genera, Chorda, Saccorhiza, and Laminaria; (2) Agareæ, with Agarum, Thalassiophyllum, Costaria, Cymathære, and perhaps Arthrothamnus. II. Les-

soniideæ, with (1) Lessonieæ and the genera Dictyoneuron, Lessonia, Postelsia, and Nereocystis; (2) Macrocysteæ, with Macrocystis. III. Alariideæ, with (1) Alarieæ, containing Alaria and Pterygophora; (2) Ecklonieæ with Ulopteryx, Ecklonia, and Eisenia; (3) Egregieæ with Egregia. A synopsis of these nineteen genera is given, and also a list of all the known species with localities. The Laminariaceæ are inhabitants of the colder waters of the globe, it is the summer temperature which seems to act as a limit to their distribution, as heat not cold is inimical to their growth, they can endure almost any degree of cold that occurs even in polar seas, but speedily die away where the waters are at all warm.

IN support of his theory that the toxic products elaborated by pathogenic bacteria partake of the nature of ferments, Dr. Uschinsky (*Centrlb. f. Bakt.* 1893) quotes some very interesting experiments made by Courmont and Doyon, published in two lectures given before the Société de Biologie in March and June last. These investigators, in their studies on tetanus-poison, point out that the toxic action of this material is not hastened by greatly increasing the quantity of toxine introduced into an animal. Thus 200 c.c. of the filtrate obtained from a tetanus-broth-culture were injected into the blood of one dog, and from 3-4 c.c. of the same filtrate into another dog; in both cases tetanus symptoms developed on the third day after the injection. These investigators also state that they were able to induce symptoms of tetanus in animals, by simply injecting some of the blood derived from an animal rendered tetanic as above, similar results being also obtained with muscle-extract. That the quantity of the toxine introduced into the system of an animal does not influence the ordinary period of incubation characteristic for each variety of animal, was confirmed by experiments made by Dr. Uschinsky on rabbits; for by the injection of from 40-50 times the usual quantity of tetanus-toxine into these animals, he was not able to hasten the appearance of the tetanus symptoms. On the other hand, he failed to confirm the remaining results obtained by Courmont and Doyon, for on injecting 6-7 c.c. of the blood of rabbits suffering from tetanus into guinea-pigs and frogs, no symptoms of tetanus made their appearance in these animals. It is possible, however, that the French investigators used larger quantities of tetanus blood for their inoculations, and that this may account for the divergence in the results obtained.

TWO contributions have recently been made towards the ætiology of the particular form of nervous disease known as delirium acutum. Early in the year Prof. Bianchi and Dr. Piccinino published a paper in the Transactions of the R. Accad. Med.-chirurg. of Naples, entitled "Sull'origine infettiva di una forma di delirio acuto," and in the *Centralblatt f. Bakteriologie*, vol. xiv. No. 16, Dr. Rasori has described the results of his observations on the ætiology of a particular case of delirium acutum which passed into his hands in the Bologna lunatic asylum. The investigations were, however, carried out in Prof. Tizzoni's laboratory, and under his direction. The clinical aspect of the case suggested some source of infection as the primary cause of the disease, and at the autopsy some of the fluid underneath the dura mater was removed and inoculated into sterile bouillon and agar-agar respectively, and kept at 37° C. In both these media bacterial growths made their appearance, which were found to be due to a small bacillus, the microscopic and macroscopic description of which is shortly given. The next step was to ascertain if this organism was endowed with pathogenic properties, and for this purpose ¼ c.c. of a pure culture in broth of the bacillus was introduced, with the usual rigid antiseptic precautions, under the dura mater of a healthy rabbit. This animal died in two days, and the bacillus was found in large numbers in the blood and in the marrow taken direct from the brain and spinal cord. Similar results were obtained when the organism was introduced subcutaneously or into the nasal membrane, the bacillus being detected in the nerve substance as well as in the blood of the animal. The organism was, therefore, possessed of virulent pathogenic properties, being able to exist and multiply in the body of the rabbit, and by elaborating some toxic substance to induce its death in from one and a half to six days, according to the point selected for inoculation. Dr. Rasori, in making this preliminary communication, reserves to himself the task of trying to trace out the special circumstances which favour this bacterial infection, and the manner in which it may gain access to the human subject.

AN excellent photograph of the late Prof. Tyndall appears in Part 52 of "The Cabinet Portrait Gallery," published by Messrs. Cassell & Co., and is accompanied by a sketch of his career.

IN a Supplementary Paper, just issued by the Royal Geographical Society, Messrs. D. G. Hogarth and J. A. R. Munro give an account of "Modern and Ancient Roads in Eastern Asia Minor."

WE have received the *Monthly Weather Review* for July, 1893, prepared under the direction of Mr. A. Pedler, F.R.S., meteorological reporter to the Government of India.

THE third volume of Prof. Blake's "Annals of British Geology," 1892 (Dulau and Co.), has appeared. In previous volumes an objectionable feature was the insertion of criticisms among the abstracts of papers, but in this Prof. Blake's opinions are collected together in the form of an introductory review. We are afraid that the following extract from the preface heralds the death of the "Annals": "On the reception accorded to the present volume depends the continuance of the publication; the experimental stage is ended. The co-operation, therefore, is invited of all those who desire a record of geological literature of any kind, for the 'Geological Record' having fallen through, and the 'Year Book of Science' being discontinued, if these 'Annals' cannot be put on a firm basis the only remaining hope would be that the Geological Society should undertake a 'Record' at their own expense, by the aid of paid recorders."

AT the November meeting of the Institution of Engineers and Shipbuilders in Scotland, Prof. J. H. Biles read a paper on "The Strength of Large Ships," in which he gave the results of a series of calculations undertaken with a view of determining the relative stresses upon ships of more than 400 feet in length. Capt. J. Bain gave an account of experiments made with six large screw steamers to test "The Effect of Reversing the Screw of a Steamship upon the Steering." His experiments lead him to the following conclusions:—(1) If the helm is put hard aport on board a screw steamer, with a right-handed propeller, going full speed, or nearly full speed, ahead, and at the same instant the engines are reversed full speed, her head (provided there are no disturbing influences present) will cant to port instead of to starboard. (2) If the helm is put, or rather allowed to run hard astarboard, the instant the engines are reversed full speed ahead her head will cant to starboard as if *on a pivot*. (3) If a steamer, with a right-handed screw, going full speed ahead, has another vessel close to on her starboard bow, and in trying to clear her the helm is put hard astarboard and the engines reversed full speed, a collision is almost certain. With regard to the *Victoria* disaster Capt. Bain says: Had both the vessels started from their respective divisions at, say, under half speed ahead, with the port screw reversed on board the *Victoria*, and the starboard screw reversed on board the *Camperdown*, while the other screw on each of them was

kept at full speed ahead, the collision would have been averted.

A FURTHER communication concerning the explosive metallic derivatives of acetylene is contributed to the *American Chemical Journal* by Dr. Keiser. He has previously shown that the compounds obtained by the action of acetylene upon ammoniacal solutions of cuprous chloride and silver nitrate possess the composition C_2Cu_2 and C_2Ag_2, and that they are to be regarded as substitution products of the hydrocarbon. The action of acetylene upon aqueous and alkaline solutions of mercuric salts has since been studied, and the results are now published. When acetylene acts upon silver nitrate, either in aqueous or ammoniacal solution, the same product, C_2Ag_2, appears to be produced. But in the case of mercuric salts the action appears to be essentially different in aqueous and alkaline solutions. When acetylene is led through a solution of mercuric chloride in water, a white granular precipitate is produced, which is not explosive after drying, and which does not dissolve in dilute acids with evolution of acetylene gas. This compound contains chlorine, and is represented by the formula $C_2(HgCl)_2$. If, however, acetylene is passed into an alkaline solution of a mercuric salt, such as Nessler's solution, mercuric iodide dissolved in potassium iodide with the addition of caustic potash, a white flocculent precipitate is obtained, which when dry is extremely explosive and dissolves in dilute hydrochloric acid with evolution of acetylene. It is analogous in all its properties to the silver and copper compounds, and is a metallic substitution product of the same type, C_2Hg. This compound can only be obtained in the pure state by the use of pure acetylene, such as that prepared by treating ethylene dibromide with alcoholic potash. Decomposition of the substance commences at about 100°, and when it is rapidly heated to a temperature slightly higher than this it explodes with extreme violence, leaving a small residue of finely divided carbon and mercury. It is particularly interesting to learn that when the substance is treated with an alcoholic solution of iodine it unites with the latter, slowly even at the ordinary temperature and rapidly at the temperature of a water-bath, forming di-iodo-acetylene, C_2I_2. This compound upon standing a short time polymerises, and the polymer separates in the form of crystals which melt at 187° and appear to be hex-iodo-benzene, C_6I_6.

IN the course of an investigation concerning the atomic weight of copper, Messrs. Richards and Rogers, of Harvard University, have observed that cupric oxide prepared by ignition of the nitrate always contains a considerable amount of occluded gas, chiefly nitrogen, while that prepared from the carbonate invariably shows no sign of occluded gas. This fact is of considerable importance inasmuch as the previous determinations of the atomic weight of copper are affected by it and will be rendered more or less inaccurate. It is no new observation, however, for it was pointed out by Frankland and Armstrong as long ago as 1868, but appears to have been largely overlooked. The Harvard chemists show, moreover, that the phenomenon is also exhibited by oxides of zinc, nickel, and magnesium, when prepared by ignition of the nitrate. In the case of magnesia the amount of occluded gas is extraordinarily large, exceeding a hundred cubic centimetres from ten grams of oxide. Hence it is considered necessary that the atomic weights of these metals should be subjected to revision, taking account of these facts, and until this is done the values hitherto accepted can only be considered as approximate.

THE additions to the Zoological Society's Gardens during the past week include a Mona Monkey (*Cercopithecus mona*, ♀) from West Africa, presented by Mrs. Frances Bell; a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. Henry Vane; three Black-backed Jackals (*Canis mesomelas*) from South Africa, presented by Mr. J. Matcham; four Bernicle Geese (*Bernicla leucopsis*), 2 ♂, 2 ♀) European, a Variegated Sheldrake (*Tadorna variegata*) from New Zealand, presented by Sir Henry Peek, Bt.; a Little Auk (*Mergullus alle*) British, presented by Mr. J. W. C. Stares; two Adorned Ceratophrys (*Ceratophrys ornata*) from Buenos Ayres, presented by Miss Mildred FitzHugh; a Mozambique Monkey, (*Cercopithecus pygerythrus*) from East Africa, deposited; six Smooth-clawed Frogs (*Xenopus lævis*) hatched in the Gardens.

OUR ASTRONOMICAL COLUMN.

SMALL DISTANCES MEASURED WITH THE HELIOMETER.—As the filar micrometer measures very precisely distances of a few seconds, so with equal accuracy does that important of modern instruments, the heliometer, measure distances ranging from a few minutes up to one or two degrees. With the former instrument one brings the thread (moved by the micrometer head) first to one side of the star and then to the other; or, if one has two threads, one places the star half-way between them, and thus reads off the distance. With the heliometer the distances are read off the scale at the object-glass end (from the eye end), the images of the two stars cast by the movable half of the object-glass being placed symmetrically first on one, and then on the other side of the images from the fixed half.

In the measurement of small distances with the heliometer it has been found that nearly every observer measures the distances too small, thus a small positive correction has to be applied to the observations. As an instance of the magnitude of the corrections to be added or subtracted for various distances, we give the following table:—

Mean distance	CAPSTADT.			Yale Obs.	GÖTTINGEN.	
	Gill.	Finlay.	Jacoby.	Chase.	Schur.	Ambronn.
″	″	″	″	″	″	″
1000	+0·03	+0·07	+0·18	+0·14	+0·20	+0·14
2000	+0·01	0·00	+0·13	+0·08	+0·03	+0·02
3000	+0·01	−0·04	+0·13	+0·08	+0·09	+0·11
4000	+0·01	0·00	0·00	−0·01	−0·08	−0·11
5000	−0·06	−0·05	−0·15	−0·10	−0·01	−0·15
6000	−0·04	−0·13	−0·21	−0·18	−0·12	−0·22
7000	0·00	0·12	−0·12	−0·08	−0·07	−0·21

The necessity of such a correction has long been known, but its cause is yet unexplained, although suggestions, such as that of Dr. Gill, have been put forward. In *Astronomische Nachrichten*, No. 3197, Prof. Wilhelm Schur gives an interesting account of his investigations, which had for their aim the determination of the source of this error. Observations showed him that the explanation suggested some time back by Dr. Gill was not valid, at any rate for the Göttingen heliometer; it was finally thought that an explanation might be found by supposing an irregular guidance to occur to those parts of the instrument which carry the objective, but on investigation it was found that such was most improbable. Irregularity in the objective slides themselves was also eliminated, as the magnitude of the error necessary to produce such a large difference in the distance measured was too large to be at all considered. In the paper Prof. Schur is led to discuss some of the measurements made in the triangulation of the Præcipe, and he refers to the method he adopted to bring all the measures into harmony. Three ways were open to him to satisfactorily accommodate the distances in this work, they being, in the measurements of the three arcs, the employment of quantities which are too small to be of no account in the measures of distances in the large quadrilateral. Development of the formula on the assumption (as the observations indicate) that at the distance 1300″ a maximum in the correction occurs, and for 0″ and 5000″ the "verbesserung" is 0, and α is assumed to be 0″·473. And lastly, the computation of the "verbesserung" after the expression 0″·264 s., which assumes a change in the scale value, which change, although inadmissible for large distances, brings, in the case of the distances here concerned, the measurements into a more satisfactory concord.

The Tail of Comet Brooks (c. 1893).—The tail of this comet seems to have undergone some interesting changes, and the following brief descriptions from two well-known observers will show the different appearances observed. Mr. Brooks describes the tail on October 21, 17h, as having a sharp curve close to the head towards the south and accompanied by a faint secondary tail, issuing from the head at an angle of 30° to the main tail towards the north (*Astronomy and Astrophysics* for December). On November 4, the tail assumed its usual straight form, but on November 9, 17h, it was straight for a length of half a degree from the head, where it became forked, the larger portion curving gracefully to the south, the fainter part straight, or nearly so, branching to the north, the two branches making an angle with each other of about 25°. Prof. Barnard, who has obtained several pictures, found that they showed undoubtedly that on October 21 the tail had encountered some outside or obstructive medium which badly shattered it. Rapid and some very remarkable changes in position angle were also gathered from an examination of the plates. The advantage of photography for obtaining cometary photographs, and especially for making analyses of the tails, will be at once grasped when one considers that Prof. Barnard, with the 12 in., could not trace the tail even to a distance of 1°, while the photographs taken with the Willard lens (6 in. aperture, 31 in. focus) showed it fully for 10°.

Hydrogen Envelope of the Star D.M. +30°3639.—Prof. W. W. Campbell, in the December number of *Astronomy and Astrophysics*, communicates a very important observation with regard to the spectrum of one of the Wolf-Rayet stars. The star in question is of the 9·3 magnitude, D.M. +30°3639, and its spectrum is very rich in bright lines. The most striking features of the visual spectrum have been noted as the bright line λ 5694, the bright blue band at λ 4652, and the very bright hydrogen line $H\beta$. By arranging the spectroscope so that each of these different parts of the spectrum is in focus, the line λ 5694 is seen as "a very small image of the star." The band at λ 4652 is "broad and lies wholly upon the narrow continuous spectrum," the $H\beta$ line observed with a narrow slit "is a long line extending to a very appreciable distance on each side of the continuous spectrum," and with an open slit is "a large circular disc 5″ in diameter." Other hydrogen lines $H\gamma$ and $H\alpha$ also exhibit the same peculiarities. The explanation of this appearance is that the star in question must be surrounded by an envelope of incandescent hydrogen, for other lines in the same spectrum are not so changed. It is remarked also that in other stars of the same type no such image has been observed.

"L'Astronomie" for December.—The December number of this journal commences with a most interesting article by Dr. Janssen on the Observatory at Mont Blanc. The article itself contains nothing of which our readers have not been informed in the previous columns of Nature unless it be the illustration showing the summit of the mountain with the observatory "in winter." Two good illustrations of the appearance of the sun during the last total eclipse of the sun (April 16, 1893), the clichés of which were obtained by M. Schœberle and Prof. Deslandres. "Around the world of Jupiter in ten hours" is the title of a series of observations made at the observatory of Juvisy by M. Eugène Antoniadi. The writer gives twelve drawings of this planet, as made during this period, showing the various surface markings which were brought to view by rotation. Amateurs and others who at this time are observing this planet will find these drawings a most useful help in recognising many markings. The red spot is described as excessively pale: "Elle est colorée en rose; ses regions centrales sont claires, ses bords plus sombres; elle est entourée d'une auréole blanchâtre."

GEOGRAPHICAL NOTES.

The death of Dr. H. Rink, on December 15, removes the greatest authority on Greenland and the Eskimo. His life-long devotion to the problems of the Arctic people gained for him the esteem of all geographers.

Reuter's Agency announces that information has been received from Baron Toll to the effect that up to October 25 Dr. Nansen had not called at the Olenek river. This is practically decisive news that Dr. Nansen found the sea so open that he determined to push northward without delaying to call anywhere; and it is improbable that we shall hear more of the intrepid traveller until we receive his own report of success or failure.

Dr. Murray's paper on the renewal of Antarctic exploration will be published in the January number of the *Geographical Journal*, which commences the third volume. It will be accompanied by a series of letters from distinguished foreign oceanographers and naturalists, strongly urging the importance of resuming systematic exploration in Antarctic seas.

Dr. Hillier has recently communicated a paper to the Vienna Academy of Sciences on the geography of the Pindus range, one of the few mountain systems of any extent in Europe which has never yet been adequately explored. He finds that the system consists of three parallel ranges, and he has unravelled the geological structure of each.

A communication to the Royal Geographical Society states that Mr. Crawshay, a Government official in British Central Africa, has recently visited the Angoni country near Lake Nyasa. He found the Nyika Plateau, which was traversed on the way, a magnificent country, inhabited by a scattered population of Anyika, living in huts built on narrow terraces on the mountain-side or in caves, and cultivating peas as an almost exclusive crop. In this district there are some fine mountains, exceeding 8,000 feet in height, the principal town of the Anyika, on the slope of Kantorongondo, being nearly 6,000 feet above the sea.

EPIDEMIC INFLUENZA.[1]

The present report, a welcome supplement to the epoch-making report on the epidemic of 1889-90, is divided into eight parts, the first seven by Dr. Parsons, and the last one by Dr. Klein. It includes statistical studies of the epidemic of 1890, an account of the recent epidemics in England and Wales, a history of influenza abroad in 1891 and 1892, considerations respecting the ætiology of the disease, notes on some clinical features of the later epidemics, reports on outbreaks in institutions, &c., remarks on the prophylaxis of the disease, and, in Dr. Klein's department, a report on influenza in its clinical and pathological aspects, to which photographic plates are appended exhibiting influenza bacilli.

Among the conclusions confirmed by the present report are the small influence of locality, or environment, and the invariably potent factors of exposure or proximity to the sick, and bad ventilation. Over and over again serious epidemics in a town or island have been traced to the arrival of one or two persons from an infected place. With regard to the later epidemics, it would appear that the contagion of the disease, scattered broadcast, had "retained its vitality, but in a suspended or inconspicuous form, perhaps by transmission from one human being to another in a succession of mild sporadic cases, perhaps in some medium external to the human body." Recrudesence has taken place chiefly in early spring and in autumn. Observers in various parts of the world have contributed their experience that the progress of influenza in a country is gradual. The most remarkable instances of rapid and wide diffusion were in the United States, especially in the Western States and to settlements far apart.

A good example of the usual manner of spread is given in Part IV. A teacher of music visited two relatives ill with influenza on April 6, and returned to his own locality, which had been hitherto unaffected. On April 9 he was attacked, but struggled through his work, and gave lessons to pupils at several houses. On April 11, ten of his pupils, and on April 12, the people with whom he lodged, developed the disease.

One medical officer states that he recollects no instance of the disease spreading from one member of a household to others where strict precautions for isolation and disinfection were taken. Unfortunately, however, it often happens that the first member attacked was not the only one who had been previously exposed to infection. Dr. Newsholme, medical officer for Brighton, states that the borough sanatorium, being very strictly isolated in every respect, escaped during the first two outbreaks, and in the third until a servant who had been absent

[1] Further report and papers on Epidemic Influenza, 1889-92. With an introduction by the Medical Officer of the Local Government Board. 1893.

returned and fell ill with influenza; strict isolation was even then successful in preventing its spread to the inmates.

Dr. Caldwell Smith's evidence as to ætiology is valuable and interesting. "It is to the life history of Pfeiffer's bacillus that we must direct our attention if we wish to understand the seemingly strange vagaries of the disease. An individual is infected by breathing at once the expired air from a person suffering from the disease, and I believe this to be the only method of infection."

The concourse of people is favourable to the spread of influenza in two ways, according to Dr. Parsons: firstly, by bringing the affected and the healthy near together; and secondly, by the poison being present in a more concentrated form in confined and vitiated air.

Among the discussions which throw light on the character of the disease, and bear upon the means of prevention, the following may be mentioned: on the degree of protection afforded to individuals and to communities by previous attacks, on the influence of occupation and of unsanitary conditions, on the connection with pneumonia, on the period of infectiousness, on the clinical features of the later epidemics, and on relapses.

The researches of Dr. Klein, in respect to the effect of inoculation upon animals, gave results for the most part negative. His affirmative results, however, were "in full agreement with the results obtained by Pfeiffer and Kitasato." The bacillus was always abundantly present in the bronchial secretion of patients suffering from influenza, diminishing in number as the disease abated.

"It is to be feared," wrote Dr. Parsons, "that the contagion of influenza is still domiciled among us, and that a renewal of its epidemic activity within the next few years is by no means improbable." The expected revival is now only too apparent. A certain proverb declares, with the rashness of its class, that the man once bit is twice shy. In a literal sense, the saying may contain a good deal of truth, but to nations, or aggregations of individuals, it is quite inapplicable. The development of common sense for common action against these evils has still to take place. This country has now passed through three severe epidemics of influenza within four years, each outbreak drawing many sad maladies in its train, prostrating hundreds of thousands of breadwinners, cutting short many illustrious lives, and crippling many for years to come, and we are now running into a fourth epidemic in London, without any great organised attempt being made to counteract it.

The provisional memorandum of the Local Government Board, issued on January 23, 1892, impressed upon the public the fact that in its epidemic form influenza is an eminently infectious complaint, communicable in the ordinary personal relations of individuals with each other, that separation of the sick from the healthy should as far as practicable be carried out, that rooms, &c. should be disinfected, and that ventilation should receive special attention.

It would be some defence against a serious recrudescence of the pest if this memorandum, or an abstract of it, were supplied to every householder on the first threatenings of an outbreak in any locality. In his article on prophylaxis, Dr. Parsons remarks on the difficulties which would frustrate any measures of notification and isolation on a large scale, but suggests that notification, with fees for early cases only, might be tried in certain districts, and that such a measure should be adopted "in the interval before another epidemic." So much experience has been gained in distinguishing the symptoms of influenza from those of other ailments, that the difficulty of diagnosis cannot now be an insuperable bar to attempts at prevention. It is well to remember that the pecuniary cost of prevention cannot be compared with the loss to the country by an epidemic, for this has been proved to amount to millions.

Among places and means of infection which may cause much mischief, but are not noticed in this volume, are bakers' shops, in which the baker or attendant suffers from influenza or severe cold; booking offices, post offices, banks, &c. in which the mouth and the ledger, &c. are in multiple communication; letters written and fastened by patients; and, most of all, railway carriages packed full and with windows closed, daily conveying vast numbers of people to and from the city, and containing perhaps the most organically polluted air which can easily be found in a civilised country.

The report closes with an interesting statement respecting the immunity of animals, including monkeys, at the Zoological Gardens.

R. RUSSELL.

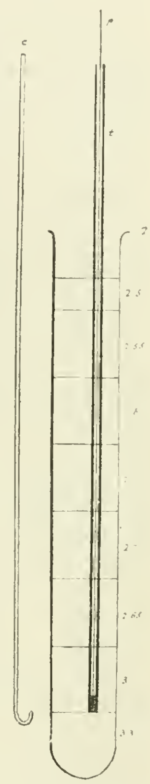
ON A METHOD OF SEPARATING THE MINERAL COMPONENTS OF A ROCK.

IT is told of a famous German petrographer, that whenever appealed to by a student in difficulties over a problematical mineral in a rock-slice, his invariable advice was "Get it out."

It is hard dispassionately to reflect on the sufferings to which this simple process of "getting it out" have given rise. All we petrographers have passed through the vale! May we now indulge the pious hope that the following simple apparatus may bring some mitigation to the ordeal? It will certainly save a good deal of time and trouble when only small quantities of a particular mineral are required; enough, that is, for a blowpipe analysis, a flame test, and microscopical examination.

A large test-tube (see Fig.), conveniently six inches in length by three-quarters in diameter, is filled with heavy solution, graded from specific gravity 3·3 to 2·5, so as to form after standing a diffusion column, as already described in NATURE, vol. xliii. p. 404, 1891. It is not necessary to wait till the change in density of the column is uniform from top to bottom; by introducing a sufficient number of specific gravity indexes the column is mapped out into a succession of lengths, within the limits of each of which the change of density is practically uniform, certainly sufficiently so for mineral determinations.

A fragment of the rock to be examined, about the size of a hazel-nut, is powdered in the usual way, sifted and washed, dried and then introduced into the diffusion column. Separation of the constituent minerals at once begins to take place, and in the course of a few hours is complete. Each species of mineral is then floating in liquid of its own specific gravity; the next problem is to get it out. A pipette as commonly used is not sufficient, for as it is introduced grains of minerals from other zones than that sought for, adhere to its sides; on removing the finger, the sudden inrush of fluid carries with it grains from surrounding zones, and finally on drawing up the pipette, fluids of zones lying above that to which it has descended displace the heavier fluid it already contains, carrying with them suspended grains, and thus bringing about the mixture which it is our desire to prevent.



A test-tube containing a diffusion column. The figures at the side indicate corresponding specific gravities: *t*, pipette fitted with a piston *p*; *c*, crook by which the lower end of the pipette may be plugged.

With very little trouble these difficulties may be completely overcome. To prevent the sudden inrush of fluid the pipette, which should be of small calibre (in my experiments it measures 1·5mm.), is fitted with a piston (*p*). This may be very simply made by winding a little unravelled cotton thread round the end of a stem of Esparto grass, such as is sold for cleaning tobacco-pipes. The piston is pushed down to the bottom of the pipette, which is then ready for use.

To extract grains from any zone the pipette is slid down into the diffusion column till its lower end is just immersed in the zone; a gentle shake given to it as it passes through the solution will serve to detach adhering particles; the piston is then slowly raised, and the fluid with its floating mineral grains quietly follows it, the other zones remaining undisturbed. To prevent the fluid of higher zones entering the pipette as it is withdrawn, it is necessary to plug its lower end; no very tight closure is necessary, since the piston, which now lies at the upper end of the pipette, by excluding the air ensures the retention of the contained column of fluid; all that is needed is a stopper, which will exclude solid particles. A very thin glass rod is rounded off at one end, which is then bent upwards into the form of a crook (*c*). The crook is let down into the diffusion column till its upward pointing lower end lies beneath the open extremity of the pipette, which it completely blocks up on being

raised into position. The pipette with the crook is then taken out of the fluid, and inverted. The crook is laid aside, and the outside of the pipette cleaned with blotting-paper, by which all adhering foreign grains are removed. The pipette now contains a pure gathering of the mineral required, and it only remains to discharge its contents, and this is of course accomplished by pushing down the piston.

Minerals may thus be removed from every zone of a diffusion column; and all the species which enter into the composition of a rock, except of course the very heaviest, may be separately obtained, with their specific gravity determined as an incident of the process.

In this absurdly simple fashion "getting it out" ceases to be a penance, and becomes a pleasure. W. J. SOLLAS.

THE CLOUDY CONDENSATION OF STEAM.[1]

THE air, as every one knows, is composed almost entirely of the two gases, oxygen and nitrogen. It also contains small quantities of other substances, of which the chief are carbonic acid gas and water vapour, and it is the latter of these constituents, water vapour, or "steam," as it is sometimes called, that will principally concern us this evening.

The quantity of invisible water vapour which the air can at any time take up depends upon the temperature; the higher the temperature of the air the more water it can contain. The proportion, however, never exceeds a few grains' weight of water to a cubic foot of air. Air at any temperature, containing as much water as it can possibly hold, is said to be "saturated," while the temperature at which air containing a certain proportion of water becomes saturated is called the "dew point."

The large glass globe, upon which the beam from the electric lantern is now directed, contains ordinary air, kept in a state of saturation, or nearly so, by the presence of a little water. You will observe that although heavily laden with water vapour the air is perfectly transparent. If, now, we turn a tap, and so connect the globe with an exhausted receiver, the air expands and becomes colder; the space inside the globe is no longer able to hold the same quantity of water as before in the form of vapour, and the excess is precipitated as very finely divided liquid water, which fills the globe and is perfectly visible as a cloud or mist. In a few minutes the cloud disappears, partly, no doubt, because some of the particles of water have fallen to the bottom of the vessel, but chiefly because the air becomes in time warmed up to its original temperature (that of the room), and the suspended water is converted back again into invisible vapour.

I once more rarefy the air, and admit a fresh supply while holding the flame of a spirit lamp near the orifice of the inlet pipe, so that some of the burnt air is carried into the interior of the globe. When the air is again expanded a cloud is formed which is far more dense than the others were. It appears on examination that the increased density of this cloud is not due to the condensation of a greater quantity of water. Little, if any, more water is precipitated than before. But the water particles are now much more numerous, their increased number being compensated for by diminished size. Within certain limits, the greater the number of particles into which a given quantity of water is condensed, the greater will be the apparent thickness of the mist produced. A few large drops will not impede and scatter light to the same extent as a great number of small ones, though the actual quantity of condensed water may be the same in each case.

Then comes the question, why should the burnt air from the flame so greatly increase the number of the condensed drops? An answer, though perhaps not quite a complete one, is furnished by some remarkable experiments made by M. Coulier, a French professor, nearly twenty years ago. He believed his experiments showed that water vapour would not condense at all, even at temperatures far below the dew point, unless there were present in the air a number of material particles to serve as nuclei around which the condensation would take place. All air, he says, contains dust; and anything that increases the number of dust particles in the air increases the density of the condensation by affording a greater number of nuclei. Air in which a flame had been burnt he supposed to be very highly charged with finely-divided matter, the products of combustion, and thus rendered extraordinarily "active" in bringing about condensation. And that, according to Coulier's view, is the reason why such a dense fog was formed when air which had been contaminated by the spirit flame was admitted to our globe.

On the other hand, air, even burnt air, which has been filtered through tightly packed cotton wool, is found to be perfectly inactive. No cloud or mist will form in it, however highly it may be supersaturated. Coulier explained this fact by supposing that the process of filtration completely removed all dust particles from the air.

The experiments of Coulier were repeated and confirmed by Mascart. The latter also made one additional observation which may very probably turn out to be of great importance. He found that ozone, or rather, strongly ozonised air, was a very active mist producer, and that unlike ordinary air, it was not deprived of its activity by filtration.

Four or five years later, all the facts which had been noticed by Coulier, and others of an allied nature, were independently discovered by Mr. Aitken, who has devoted much time and study to them, and made them a foundation of an entirely new branch of meteorology.

Later, perhaps, we may see reason to doubt whether all the conclusions of Coulier and Aitken are quite accurate, especially as regards the action of so-called products of combustion.

Every one has noticed how dense and dark a thundercloud is. It shuts out daylight almost as if it were a solid substance, and the glimmer that penetrates it is often imbued with a lurid or copper-coloured tint.

I had always found it rather difficult to believe that these peculiarities were due simply to the unusual extent and thickness of the clouds, as is commonly supposed to be the case, and it occurred to me about three years ago, that perhaps some clue to the explanation might be afforded by the electrification of a jet of steam. On making the experiment I found that the density and opacity of the jet were greatly increased when an electrical discharge was directed upon it, while its shadow, if cast upon a white screen by a sufficiently strong light, was of a decidedly reddish-brown tint.

As a possible explanation of the effect I suggested that there might occur some action among the little particles of water of a similar nature to that observed by Lord Rayleigh in his experiments upon water jets. A jet of water two or three feet long is made to issue in a nearly vertical direction from a small nozzle. At a certain distance above the nozzle the continuous stream is found to break up into separate drops, which collide with one another, and again rebounding, become scattered over a considerable space. But when the jet is exposed to the influence of an electrified substance, such as a rubbed stick of sealing-wax, the drops no longer rebound after collision, but coalesce, and the entire stream of water, both ascending and descending, becomes nearly continuous.

There is one other point to which I wish to direct your particular attention. If the sealing-wax, or better, the knob of a charged Leyden jar, is held very close to the jet, so that the electrical influence is stronger, the separate drops do not coalesce as before, but become scattered even more widely than when no electrical influence was operating. They become similarly electrified and, in accordance with the well-known law, repel one another.

We will now remove the water jet, and in its place put a little apparatus for producing a jet of steam. It consists of a half-pint tin bottle, through the cork of which passes a glass tube terminating in a nozzle. When the water in the bottle is made to boil, a jet of steam issues from the nozzle, and if we observe the shadow of the steam jet upon the screen we shall see that it is of feeble intensity and of a neutral tint, unaccompanied by any trace of decided colour. A bundle of needles connected by a wire with the electrical machine is placed near the base of the jet, and when the machine is worked electricity is discharged into the steam. A very striking effect instantly follows. The cloud of condensed steam is rendered dense and dark, its shadow at the same time assuming the suggestive yellowish-brown colour.

I at first believed that we had here a repetition, upon a smaller scale, of the phenomenon which occurs in the water jet. The little particles of condensed water must frequently come into collision with one another, and it seemed natural to suppose that, like Lord Rayleigh's larger particles, they rebounded under ordinary circumstances, and coalesced when under the influence

[1] Extracted from a lecture on "Fogs, Clouds, and Lightning," delivered at the Royal Institution on May 5.

of electricity. The great majority of the small particles ordinarily formed consisted, I thought, of perhaps only a few molecules, which were dispersed in the air, and again converted into vapour without ever having become visible, while the larger particles formed by their coalescence under electrical action were of such dimensions as to impede the more refrangible waves of light. Hence the brownish-yellow colour.

Other explanations have been proposed. There is the molecular shock theory of the late R. Helmholtz (who, as it turned out, had studied electrified steam jets before I made my own experiments). I shall refer to his speculation later. And there is the dust-nucleus theory, which no doubt appears a very obvious one.

Though I knew that my own hypothesis was not quite free from objection, neither of these alternative ones commended itself to me as preferable; and so the matter rested until a few months ago, when the steam jet phenomenon was discussed anew in a paper communicated to the Royal Society by Mr. Aitken. Mr. Aitken said that he did not agree with my conjecture as to the nature of the effect. This led me to investigate the matter again, and to make some further experiments, the results of which have convinced me that I was clearly in error. At the same time it seems to me that the explanation which Mr. Aitken puts forward is little less controvertible than my own. Mr. Aitken's explanation of the phenomenon is, like mine, based upon Lord Rayleigh's work in connection with water-jets, but, unlike mine, it depends upon the experiment which shows that water particles when strongly electrified are scattered even more widely than when unelectrified. He believes, in short, that electrification produces the effect, not by promoting coalescence of small water particles, but by preventing such coalescence as would naturally occur in the absence of electrical influence. In the electrified jet, he says, the water particles are smaller, but at the same time more numerous; thus its apparent density is increased.

The chief flaw in my hypothesis lies in the fact that the mere presence of an electrified body like a rubbed stick of sealing-wax, which is quite sufficient to cause coalescence of the drops in the water jet, has no action whatever upon the condensation of the steam jet. There must be an actual *discharge* of electricity. But it is by no means essential, as Mr. Aitken assumes, that this discharge should be of such a nature as to electrify, positively or negatively, the particles of water in the jet. If, instead of using a single electrode, we employ two, one positive and the other negative, and let them spark into each other across the jet, dense condensation at once occurs. So it does if the two discharging points are removed quite outside the jet. A small induction coil giving sparks an eighth of an inch in length causes dense condensation when the electrodes are more than an inch distant from the nozzle and on the same level. In one experiment a brass tube two feet long was fixed in an inclined position with its upper end near the steam jet, and its lower end above the electrodes of the induction coil. In about three seconds after the spark was started dense condensation ensued, and it ceased about three seconds after the sparking was stopped. No test was needed, though in point of fact one was made, to show that the steam was not electrified to a potential of a single volt by this operation. And the time required for the influence to take effect showed that whatever this influence might be it was not induction.

The inference clearly is that in some way or other the action is brought about by the air in which an electrical discharge has taken place, and not directly by the electricity itself. The idea has no doubt already occurred to many of you that it is a dust effect. Minute particles of matter may be torn off the electrodes by the discharge, and form nuclei upon which the steam may condense. The experiments of Liveing and Dewar have indeed shown that small particles are certainly thrown off by electrical discharge, and the idea that such particles promote condensation appears to be supported by the fact that if a piece of burning material, such as touch-paper, is held near the jet so that the products of combustion can pass into it, thick condensation is produced.

From a recent paper by Prof. Barus, published in the *American Meteorological Journal* for March, it appears that he also is of opinion that such condensation is in all cases due to the action of minute dust particles. Yet it is remarkable that Mr. Aitken, the high priest and chief apostle of the philosophy of dust, gives no countenance to the nucleus theory. He does not even advert to its possibility. I imagine that his experiments have led him, as mine have led me, to the conclusion that it is untenable. And this not only in the case of electrical discharge, but also in the case of burning matter.

If we cause an electrical discharge to take place for some minutes inside a suitably arranged glass bottle, and then, ten or fifteen seconds after the discharge has ceased, blow the air from the bottle into the steam jet, the condensation is not in any way affected. Yet the dust could not have subsided in that time. And again, if we fill another large bottle with dense clouds of smoke by holding a bundle of burning touch-paper inside it, and almost immediately after the touch-paper is withdrawn, force out the smoke-laden air, through a nozzle, upon the jet—you can all see the black shadow of the smoke upon the screen—nothing whatever happens to the jet. Yet a mere scrap of the paper which is actually burning, though the ignited portion may not be larger than a pin's head, at once darkens the jet. Dead smoke (if I may use the term) exerts little or no influence by itself: there must be incandescent matter behind it. The question naturally arises, whether incandescent matter may not be sufficient of itself, without any smoke at all. We can test this by making a piece of platinum wire red-hot and then holding it near the jet. It is seen to be quite as effective as the burning touch-paper. Yet here there can be no nuclei formed of products of combustion, for there is no combustion; there is simply ignition or incandescence.

One other point I may mention. It is stated by Barus, in the paper above referred to, that the fumes given off by a piece of phosphorus constitute a most efficient cause of dense condensation. This is true if they come directly from a piece of phosphorus; but if phosphorus fumes are collected in a bottle and then directed upon the jet, all traces of unoxidised phosphorus being first carefully removed, they are found to be absolutely inoperative. Phosphorus in air can hardly be said to be incandescent, though it is luminous in the dark; but it appears to act in the same manner as if its temperature were high.

All these facts seem to indicate that the several causes mentioned, electrical, chemical, and thermal, confer upon the air in which they act some temporary property—certainly not due to mere inert dust—in virtue of which it acquires an abnormal power of promoting aqueous condensation.

I thought that possibly some clue as to the nature of this property might be obtained by observing how some other gases and vapours behaved; but though the experiments I made perhaps tend to narrow the dimensions of the mystery, I cannot say that they have completely solved it. Indeed some of the results only introduce additional perplexities.

One of the most natural things to try is hydrochloric acid, which is known to have a strong affinity for water. If we heat a little of the acid solution in a test tube, closed with a cork, through which a glass tube is passed, and direct the issuing stream of gas upon the jet, the densest condensation results. The vapours of sulphuric and nitric acids also cause dense condensation, and I suppose both of these have an affinity for water. But so also, and in an equally powerful degree, does the vapour of acetic acid; yet the affinity of this acid for water, as indicated by the heat evolved when the two are mixed, is very small.

Ammonia gas, when dissolved in water, causes the evolution of much heat. Yet a stream of this gas directed upon the jet has no action.

Ozonised air, which Mascart found so effective in his experiments with the closed vessel, is quite inoperative with the steam jet. Equally so is the vapour of boiling formic acid, which I believe is chemically a much more active acid than acetic, and has a lower electrical resistance. (See Table.)

CONDENSATION OF STEAM JET.

Active.

Air, oxygen, or nitrogen, in which electrical discharge is occurring.

Burning and incandescent substances.
Fumes from phosphorus.
Hydrochloric acid.
Sulphuric acid vapour.
Nitric acid vapour.
Acetic acid vapour.

Inactive.

Air, &c., in which electrical discharge has ceased for about ten seconds.

Smoke without fire.
Bottled phosphorus fumes.
Ammonia.
Ozone.
Steam.
Alcohol vapour.
Formic acid vapour.
Sulphurous acid.

It seems that we have here a pretty little problem which might, perhaps, be solved without much difficulty by a competent chemist, but which quite baffles me.[1] Is it possible that the condensing vapours may contain dissociated atoms?

To return to the electrical effect. There are only two kinds of chemical change that I know of which could be brought about in air by an electrical discharge. Either some of the oxygen might be converted into ozone, or the oxygen and nitrogen of the air might be caused to combine, forming nitric acid or some such compound. The former of these would not account for the action of the air upon the jet, because, as we have seen, ozone is inoperative; the latter might. But if the activity of the air is due to the presence in it of a compound of oxygen and nitrogen, then it is clear that an electrical discharge in either nitrogen or oxygen separately would fail to render those gases active.

I arranged a spark bottle, inside which an induction-coil discharge could be made to take place; two bent tubes were passed through the cork, one reaching nearly to the bottom for the ingress of the gas to be tested, the other, a shorter one, for its egress. The open end of the egress tube was fixed near the steam jet, and first common air, then oxygen and then nitrogen were successively forced through the bottle while the coil discharge was going on. All produced dense condensation, but I thought that oxygen appeared to be a little more efficient than common air, and nitrogen a little less.

This last experiment points to a conclusion to which at present I see no alternative. It is that the action on the jet of an electrical discharge is due in some way or other to dissociated atoms of oxygen and nitrogen. There is nothing else left to which it *can* be due.

So far as Robert Holmholtz's explanation coincides with this conclusion, I think it must be accepted as correct. As to the precise manner in which he supposed the dissociated atoms to act upon the jet, it is more difficult to agree with him. He thought that the abnormal condensation was a consequence of the molecular shock caused by the violent recombination of the dissociated atoms in the supersaturated air of the jet, the action being analogous to that which occurs when a supersaturated solution of sulphate of soda, for example, is instantly crystallised by a mechanical shock.

To me this hypothesis, ingenious as it is, seems to be more fanciful than probable, but I can only hint very diffidently at an alternative one. To many chemical processes the presence of water is favourable or even essential. Is it possible that the recombination of free atoms may be assisted by water? And is it possible that dissociated atoms in an atmosphere of aqueous vapour may obtain the water needed for their union by condensing it from the vapour?

According to Holmholtz, flames and incandescent substances generally cause dissociation of the molecules of oxygen and nitrogen in the surrounding air. This, I believe, is generally admitted. I do not know whether slowly oxidising phosphorus has the same effect.

If it is conceded that the atmospheric gases are dissociated by electrical discharges, and that the presence of such dissociated gases somehow brings about the dense condensation of water vapour, we may still regard the electrified steam jet as affording an illustration of the abnormal darkness of thunder-clouds.

Perhaps another source of dissociated atoms is to be found in the ozone which is generated by lightning flashes. A molecule of ozone consists of three atoms of atomic oxygen, while one of ordinary oxygen contains only two. Ozone is an unstable kind of material, and gradually relapses into ordinary oxygen, the process being that one atom is dropped from the three-atom molecules of ozone, these detached atoms in course of time uniting with one another to form pairs. Thus two molecules of ozone are transformed into three of oxygen. A body of ozone is therefore always attended by a number of dissociated atoms which are looking for partners.

[1] Two chemists of the highest eminence have been good enough to consider the problem for me, but they are unable to throw any light upon it.

In the steam jet experiment there is not time for the disengagement of a sufficient number of isolated atoms from a blast of ozone to produce any sensible effect. But the case is otherwise when the vapour is confined in a closed vessel, as in Mascart's experiment, or when it occurs in the clouds, where the movement of air and vapour is comparatively slow.

Ozone, it will be remembered, was found by Mascart to produce dense condensation in a closed vessel even after being filtered through cotton wool. Similar filtration seems to entirely deprive the so-called products of combustion of their active property, a fact which has been adduced as affording overwhelming evidence in favour of the dust nucleus theory. Coulier himself, however, detected a weak point in this argument. He produced a flame which could not possibly have contained any products of combustion except steam, by burning pure filtered hydrogen in filtered air; yet this product was found to be perfectly capable of causing dense condensation, and, as in his former experiments, filtration through cotton wool deprived it of its activity.

These anomalies may, I think, be to a great extent cleared up if we assume that the effect of the cotton wool depends, not upon the mere mechanical obstruction it offers to the passage of particles of matter, but upon the moisture which it certainly contains, and which may act by attracting and facilitating the reunion of dissociated atoms before they reach the air inside the vessel. According to this view ozone would remain an active condenser in spite of its filtration, because free atoms would continue to be given off by it after it had passed the cotton wool. The filtration experiment should be tried with perfectly dry cotton wool, which, however, will not be easily procured, and if my suggestion is right, dry wool will be found not to deprive ordinary products of combustion of their condensing power.

To sum up. I think my recent experiments show conclusively that the dense condensation of the steam jet is not due directly either to electrical action or to dust nuclei. The immediate cause is probably to be found in dissociated atoms of atmospheric gases, though as to how these act we can only form a vague guess.

SHELFORD BIDWELL.

SCIENTIFIC SERIALS.

American Journal of Science, December.—An apparent time-break between the eocene and Chattahoochee miocene in south-western Georgia, by Raphael Pumpelly. The Red Clay Hill region, a plateau extending through the south-western part of Georgia and adjacent northern Florida, has a maximum altitude of 300 feet, is sharply limited on the north by a declivity facing the eocene flat-land country, and consists of miocene deposits resting on eocene, both of which dip about 13 feet per mile to the south. The base of the plateau is formed by the white calcareous beds of the Chattahoochee group. A time-break between the latter and the eocene is evidenced by the almost general presence of a limestone conglomerate at the base of the Chattahoochee, immediately overlying eocene fossils, and the irregularity of the surface of demarcation. It seems possible that during miocene time the present plateau of southern Georgia was outlined by submerged islands of the eocene limestone. The Gulf Stream, after the creation of the central American barrier, found its way back to the Atlantic sweeping over southern Georgia and northern Florida, and supplying the food needed to build up the great organic beds of the Chattahoochee and Chipola. The lower flat-land country of central Georgia may represent the contemporaneous course of the cold current carrying less pure water and less nutriment.—The rise of the mammalia in North America, by H. F. Osborn. This second part deals with ancient and modern placental differentiation, the succession of the perissodactyls and the artiodactyls, a discussion of the factors of evolution, and a diagram illustrating the supposed descent of the mammalia from their jurassic prototypes.—On the thoracic legs of Triarthrus, by C. E. Beecher. Some very perfect specimens of *Triarthrus Becki*, Green, in which nearly the entire calcareous and chitinous portions are represented by a thin film of iron pyrites, show, besides the antennæ already noticed, a complete series of thor-

acic legs becoming shorter towards the pygridium, but without any essential differences amongst each other. Each limb consists of two nearly equal members, one of which was evidently used for crawling, and the other for swimming. These two members and their joints may be correlated with certain typical forms of Crustacean legs among the *Schizopoda*, *Cumacea*, and *Decapoda*, and may be described in the same terms.—On the diamond in the Cañon Diablo meteoric iron and on the hardness of carborundum, by George F. Kunz and Oliver W. Huntingdon. The carborundum made by Mr. Acheson, of Pittsburg, is capable of scratching most varieties of corundum, but not the diamond.

SOCIETIES AND ACADEMIES.

LONDON.

Anthropological Institute, December 12.—Prof. A. Macalister, F.R.S., President, in the chair.—Mr. Cuthbert E. Peek exhibited some specimens of fishing-line made of human hair, some needles constructed from ribs of feather, and two message-sticks from the extreme north of Queensland.—Mr. W. L. Duckworth read a paper on the collection of skulls of Aboriginal Australians in the Cambridge University Museum, and the following papers were also read :—On an unusual form of rush basket from the northern territory of South Australia, by Mr. R. Etheridge, jun.—On a modification of the Australian Aboriginal weapon, termed the leonile, langeel, bendi or buccan, by Mr. R. Etheridge, jun.—An Australian Aboriginal musical instrument, by Mr. R. Etheridge, jun.—The Aborigines of North-West Australia, by Mr. P. W. Bassett-Smith.—Rites and customs of Australian Aborigines, by Mr. H. B. Purcell.—Japanese onomatopes and the origin of language, by Mr. W. G. Aston.

Mathematical Society, December 14.—A. B. Kempe, F.R.S., President, in the chair.—On the stability of a deformed elastic wire, by A. B. Basset, F.R.S.—This paper commences with a discussion of the different methods of determining the stability of a deformed elastic wire which is in equilibrium, and then proceeds to discuss two special problems. When a naturally straight wire is deformed into a helix having m convolutions, the helical form is unstable unless its pitch is greater than $\sec^{-1} 2m$. This result shows that it is impossible to deform the wire into a helix of *small* pitch and having a great many convolutions, such as the spring of an ordinary spring-balance, unless the wire is given a permanent set. The two special cases in which the terminal stresses consist, (1) of a thrust and a flexural couple, (2) of a couple alone, are also noticed ; and in the latter case the helix is unstable when the length of the wire exceeds half a convolution. When the natural form of the wire is a circular coil, which is unrolled and the ends joined together without twist, so that the wire forms a circular ring, the ring will be unstable when the length of the wire is greater than about one and a half convolutions. The ring is stable from displacements in its plane, and consequently will not collapse like a boiler flue ; but it is unstable for displacements perpendicular to its plane, which involve torsion as well as flexion. The stable figure will consequently consist of a closed tortuous curve.—Papers were also read by R. J. Dallas, on the linear automorphic transformations of certain quantics ; and by Dr. Hobson, F.R.S., on Bessel's functions and relations connecting them with spherical and hyperspherical harmonics.—Messrs. Love, Greenhill, Macmahon, and the President spoke on the subject of the communications.—The following papers were taken as read :—A theorem of Liouville's, by Prof. G. B. Mathews ; note on non Euclidian geometry, by H. F. Baker ; note on an identity in elliptic functions, by Prof. L. J. Rogers ; and note on a variable seven-points circle analogous to the Brocard circle of a plane triangle, by J. Griffiths.

Royal Meteorological Society, December 20.—Dr. C. Theodore Williams, President, in the chair.—Mr. C. Harding gave an account of the great storm of November 16 to 20, 1893. This storm was the most violent of recent years, and, so far as anemometrical records are concerned, the wind attained a greater velocity than has previously been recorded in the British Islands. The velocity of the wind was 96 miles in the hour from 8.30 to 9.30 p.m. on November 16 in the Orkneys, where the hurricane burst with such suddenness that it is described as like the shot of a gun, and the wind afterwards attained the very high rate of 90 miles and upwards, in the hour, for 5 consecutive hours. At Holyhead the storm was terrific ; the anemometer recorded a wind velocity of 89 miles in the hour, and it was 80 miles or above for 11 hours, while the force of a whole gale, 65 miles an hour and upwards, was maintained for 31 hours, and for 4½ days the mean hourly velocity was 54 miles. Many of the gusts were at the rate of 115 miles an hour, and at Fleetwood a squall occurred with the wind at the rate of 120 miles in the hour. The storm was felt over the entire area of the United Kingdom, and the wreck returns show that disasters occurred with almost equal frequency on all coasts. Four weeks after the storm the official records gave the total loss of life on our coasts as 335, while there were 140 vessels which had been abandoned, or had foundered, stranded, or met with other severe casualty, involving either loss of life, or saving of life by some extraneous assistance. There were 600 lives saved on our coasts by aid of the Lifeboat Institution and other means. The author has tracked the storm from the neighbourhood of the Bahamas on November 7, acress the Atlantic and over the British Islands to Central Europe on November 20.—The other papers read were on rainfull and evaporation observations at the Bombay Waterworks, by Mr. S. Tomlinson ; and on changes in the character of certain months, by Mr. A. E. Watson.

DUBLIN.

Royal Dublin Society, November 22.—Prof. W. N. Hartley, F.R.S., in the chair.—Prof. T. Johnson communicated a paper on the systematic position of the Bangiaceæ. The author, with Berthold and others, regards the group as true Florideæ, and discusses in his paper the views expressed by Schmitz, in a recent number of *La Nuova Notarisia*, against their Floridean nature—Mr. Thomas Preston gave an elementary explanation of the system of waves attending a bullet moving at a high speed through the atmosphere.—Mr. W. E. Adeney read a note on the present condition of the water in the Vartry reservoir at Roundwood, co. Wicklow, and Mr. Richard J. Moss gave the results of an examination of the Vartry water as at present supplied to Dublin.

PARIS.

Academy of Sciences, Annual Public Meeting, December 18.—M. de Lacaze-Duthiers in the chair.—After some commemorative words on the deaths of Sir Richard Owen, Kummer, and de Candolle, Foreign Associates, and those of Chambrelent, Admiral Pâris and Charcot, Members of the Academy, by the President, M. Bertrand, one of the Secretaries, announced the names of those to whom prizes had been awarded. In *Geometry*, the Prix Francœur was awarded to M. G. Robin for mathematical physics, and the Prix Poncelet to M. G. Kœnigs, for geometrical and mechanical work.—*Mechanics:* The extraordinary prize of 6000 francs offered by the Département de la Marine for contrivances increasing the efficiency of the Navy, was distributed among M. Bourdelles (for lighthouse illumination), M. Lephay (compass with luminous index), and M. de Fraysseix (system of optical pointing) ; the Prix Montyon of 700 francs to M. Flamant (hydraulics), the Prix Plumey of 2500 francs to M. Lebasteur (steam engine appliances) ; the Prix Fourneyron of 500 francs, to M. Brousset (fly-wheels).—*Astronomy:* The Prix Lalande of 540 francs, to M. Schulhof (Comets) ; the Prix Valz of 460 francs, to N. Berberich (Minor Planets). The Prix Janssen of a gold medal, to Mr. Samuel Langley (Astronomical Physics).—*Physics:* The Prix La Caze of 10,000 fr., to M. E. H. Amagat (gases and liquids).—*Statistics:* The Prix Montyon of 500 fr., to Dr. Marvand (diseases of soldiers).—*Chemistry:* The Prix Jecker of 10,000 fr., to M. D. Forcrand and M. Griner in equal parts, with a special prize to M. Gautier.—The Prix La Caze of 10,000 fr., to M. Lemoine (Phosphorus Compounds).—*Mineralogie and Geology:* The Grand Prix, to M. Marcellin Boule (The Central Plateau of France). The Prix Bordin of 3000 fr. was distributed amongst MM. Bourgeois, Gorgen, Michel, and Duboin for their researches in mineral synthesis. The Prix Delesse of 1400 fr., to M. Fayol (Commentry Strata). The Prix Fontannes of 2000 fr., to M. R. Zeiller (Palæontology).—*Botany:* The Prix Desmazières of 1600 fr., to M. C. Sauvageau (Algæ). The Prix Montagne, to MM. Cardot (Mosses) and Gaillard (Fungi).—*Agriculture:* The Prix

Morogues, to M. Millardet (Mildew).—*Anatomy and Zoology.* The Prix Thore, to M. Corbière (Muscineæ) —*Medicine and Surgery:* The Prix Montyon was distributed between MM. Huchard (Heart Diseases), Delorme (Army Surgery), and Pinard and Varnier (Pathological Atlas). The Prix Barbier, 500 fr. each to MM. Sanson (Heredity) and Dr. Mauclaire (Osteo-Arthritis). The Prix Bréant, being the interest on a sum of 100,000 francs offered for a cure for cholera, was distributed amongst MM. Netter and Thoinot (French Cholera, 1892) and MM. Grimbert and Burlureaux (Treatment of Tuberculosis by Creosote Injections). The Prix Godard of 1,000 francs, to Dr. Tourneux (Physiological Atlas). The Prix Serres of 7500 francs, to M. Pizon (Blastogenesis), with small portions to MM. Sabatier (Spermatogenesis) and Letulle (Inflammation). The Prix Bellion of 1400 francs, to Dr. C. Chabrié (Physiology of the Kidney) and Dr. Coustan (Fatigue). The Prix Mège to Dr. Herrgott (History of Obstetrics). The Prix Lallemand of 1800 francs, to M. Trolard (Venous System).—*Physiology:* The Prix Montyon of 750 francs, to M. Laulanié (Respiration) and MM. Abelous and Langlois (Renal Capsules). The Prix La Caze, of 10,000 francs, to M. d'Arsonval (Physiological Effects of Electricity). The Prix Pourat to M. E. Meyer (Renal Secretion). The Prix Martin-Damourette, of 1400 francs, to Dr. Géraud (Albuminuria).—*General Prizes:* The Arago Medal to Mr. Asaph Hall (Satellites of Mars) and Mr. E. E. Barnard (Jupiter's First Satellite). The Prix Montyon, for improvements in unhealthy industries, was divided between MM. Garros (Porcelain Manufacture) and Coquillon (Fire-damp Meter). The Prix Trémont, of 1100 francs, to M. Jules Morin for his useful hydrostatic and other inventions. The Prix Gegner of 4000 francs to M. Serret. The Prix Petit d'Ormoz of 10,000 francs, to M. Stieltjes (Mathematics), and another of the same amount to M. Marcel Bertrand (Physics of the Globe). The Prix Tchihatchef of 10,000 francs, to M. Grégoire Groum-Grschimailo (The Pamirs). The Prix Gaston Planté, of 3,000 francs, to M. Blondlot (Electric Interference). Mme. de Laplace's Prize, consisting of Laplace's works, to M. Bès de Berc, of the École Nationale des Mines.

Berlin.

Physical Society, December 1.—Prof. Schwalbe, President, in the chair.—Prof. Neesen demonstrated a method of coating aluminium with other metals. This consists in dipping the aluminium in a solution of caustic potash or soda, or of hydrochloric acid, until bubbles of gas make their appearance on its surface, whereupon it is dipped into a solution of corrosive sublimate to amalgamate its surface. After a second dipping into caustic potash until bubbles of gas are evolved, the metal is placed in a solution of a salt of the desired metal. A film of the latter is rapidly formed, and is so firmly adherent that, in the case of silver, gold, or copper, the plate can be rolled out or polished. When coating with gold or copper, it is well to first apply a layer of silver. When thus treated the aluminium may be soldered with ordinary zinc solder.—Dr. Wien spoke on the entropy of radiation.

Meteorological Society, November 7.—Prof. von Bezold, President, in the chair.—Dr. Arendt spoke on the transport of heat by means of aerial currents on the earth's surface, based on calculations derived from material provided by the Hamburg station. He first determined for each month of the year the direction and rate of the wind, from which he calculated the resultant volume of air transported over Hamburg. From the temperature and speed of the winds he obtained, under certain assumptions, numerical values for the amount of heat carried towards Hamburg during each month of the year.

December 5.—Dr. Vettin, President, in the chair.—Prof. Hellmann presented a book on "Snow-crystals," and gave an account of its contents, during which he discussed fully the structure and classification of snow-crystals. All the crystals belong to the hexagonal system, and are either flat or columnar. The radiating stars, the plates, and mixed forms belong to the first category; while the prisms and much more rare pyramids belong to the second.—Dr. H. Meyer communicated the results of his observations, made in conjunction with Prof. Köppen, on the cloud-conditions of various climates. They had rejected as valueless mean values based on determinations which are largely influenced by the personal opinion of the observer, and had in preference calculated the frequency of the occurrence of clouds. They had in this, for simplicity's sake, distinguished between three groups: (1) Complete absence of clouds; cloudiness zero. (2) Intermittent occurrence of clouds; cloudiness 1 to 9. (3) Total cloudiness represented by 10. Taking a series of stations in various climates, they had calculated and graphically represented the frequency of the three groups for the morning, midday, and evening for each month. It appeared that for Hamburg and the whole of middle and north Europe, in passing from the cold to the warm periods of both the day and year, the intermittent cloudiness increases; while complete cloudiness, which is most frequent in winter, and in the morning and evening, diminishes. Complete cloudlessness is always the most rare condition. The above characters change gradually towards the Mediterranean, even at Lesina, and more markedly at Alexandria. In mid-Asia, East Siberia, China, Batavia, and Rio Janeiro, and on the elevated station of Pike's Peak, and also on the Atlantic Ocean, the change in cloudiness in passing from winter to summer is reversed.

BOOKS and SERIALS RECEIVED.

Books.—A Text-Book on Gas, Oil, and Air-Engines: B. Donkin, Jun. (Griffin).—An Elementary Treatise on Fourier's Series: Dr. W. E. Byerly (Boston, Ginn).—Uniplanar Algebra: Dr. J. Stringham (San Francisco, Berkeley Press).—Science and Hebrew Tradition: T. H. Huxley (Macmillan).—Dictionary of the Active Principles of Plants: C. E. Sohn (Baillière).—The Country and Church of the Cheeryble Brothers: Rev. W. H. Elliot (Selkirk, Lewis).—Hints to Travellers, 7th edition (Royal Geographical Society).—The Story of the Sun: Sir R. Ball (Cassell).

Serials.—Insect Life, Vol. 6, No. 2 (Washington).—Cabinet Portrait Gallery, Part 52 (Cassell).—Astronomy and Astro-Physics, December (Wesley).—Economic Journal, December (Macmillan).—Journal of the Franklin Institute, December (Philadelphia).—Internationales Archiv für Ethnographie, Band vi. RECENT CONTRIBUTIONS TO METEOROLOGY.

Report on the Present State of our Knowledge respecting the General Circulation of the Atmosphere. By L. Teisserenc de Bort. (London: Stanford, 1893.)

On Hail. By the Hon. Rollo Russell, F.R.Met.Soc. (London: Stanford, 1893.)

Weather Lore: a Collection of Proverbs, Sayings, and Rules concerning the Weather. Compiled and arranged by Richard Inwards, F.R.A.S. (London: Elliot Stock, 1893.)

WHILE meteorologists are generally prepared to admit the salient points of the theory of the atmospheric motions as outlined by Ferrel, there are to be met discussions by various authors, accentuating not only differences in the details of the scheme, but also defects in the theory on which the general circulation of the atmosphere is based. The latest contribution to the literature of the subject illustrating these points, is from M. Teisserenc de Bort, Meteorologist to the Central Bureau, and General Secretary of the Meteorological Society of France; for this authority cannot accept, in its entirety at least, either Ferrel's deductions or his method of conducting the inquiry. Ferrel, it is well known, having deduced the equations for the horizontal motion of the atmosphere, relative to the earth's surface, applied, with effect, the condition of continuity and the law of conservation of areas, or, what would possibly be a better term, the preservation of the moment of rotation, and demonstrated the existence of an easterly motion of the atmosphere in the higher latitudes, and a westerly motion in the lower. To define the limits of these zones, Ferrel remarked that the sum of the moments with reference to the axis of the earth, of the air forming the easterly winds, ought to be equal to that of the westerly winds, and that this condition was fulfilled on a hemisphere, if the easterly winds prevailed up to 30° latitude, and westerly winds to the pole. This line of argument receives some support from the suggestion, that otherwise there would be a residual unexpended force, tending to change the velocity of the earth's rotation. But M. de Bort replies, with some force, that this argument is inadequate, because there is no evidence that the earth's rotation is uniform; and, indeed, the action of the tides and the diurnal variation of the barometric pressure, point, pretty conclusively, in an opposite direction. If the effects of friction are omitted, the author seems prepared to admit the validity of Ferrel's argument, and it would be very unjust to deny that Ferrel neglected friction altogether, or failed to modify his original result, obtained without friction. Further, Oberbeck especially has considered the effects of friction, and he has assigned a lower limit to the zone of change of direction not greatly different from Ferrel's value. Apart, however, from this point of theory, the author differs from Ferrel as to the cause of the belts of maximum pressure, north and south of the equator, and adds an explanation of the low pressure zone in latitude 55° and of the polar maximum.

But the most interesting, and possibly the most valuable portion of the paper, is the insistance on the connection traced between temperature and distribution of pressure, and the effort to explain the observed variation of pressure along parallels of latitude by the presence of thermic anomalies. The author sees in the variation of temperature over continents and seas in the same latitude, and the consequent changes in the density of the lower strata of the atmosphere, the origin of many of the irregularities that mark the isobaric curves, and a cause not inferior in its effects to the rotation of the earth in establishing the prominent features of the general circulation.

M. de Bort has also made an ingenious attempt to compute from theory the mean isobars of January and July, and to compare the results with actual observations. This is a step in advance, but the measure of success that has attended the effort must be left to the decision of individual judgment. Two approximations, or two distinct attempts, have been made. In the first, it has been assumed that at an altitude of 16,000 feet the irregularities in the distribution of the isobars disappear, and only the influence of latitude remains. Consequently the observed barometric pressure at the surface should be given by adding to the mean pressure, corresponding to the latitude, the weight of the column of air of variable density extending from the surface to this altitude. When this operation is effected, a comparison with the observed quantity discloses the fact that the computed pressures are too great, and further shows a tendency to exaggerate the barometric minimum over the North Atlantic, while it exhibits a maximum of pressure over North America which does not really exist. There is therefore, admittedly, a more marked difference in the computed isobars over continents and seas than is actually observed. Two causes are assigned for the failure to reproduce actual facts, both of which are probably operative. The one is that the density of the column of air does not diminish uniformly with the temperature, which hypothesis, for the purpose of computation, it is necessary to assume. The other is that probably the slope of the surfaces of equal pressure from the equator towards the poles is greater where the temperature is already low, than where the temperatures are high, in the upper regions of the atmosphere.

The second attempt to reproduce the observed pressure is arranged to take into account the influence of the unequal distribution of temperature upon the form of the upper isobars, and it is contended that the computed values of the surface pressure "show close analogy with those representing the isobars deduced from direct observation."

Not content with surveying the conditions of our atmospheric circulation, the author proceeds to discuss those that obtain on the planets, and submits two ideal pictures of the earth with its surrounding cloud as seen from space. These are compared with a photograph of Jupiter, but we strongly doubt whether the author gleans any additional facts in support of his views. The red spot is a conspicuous feature in this photograph, and whatever may be the true explanation of that phenomenon, the tolerable permanence of its character forbids us to ascribe it to atmospheric circumstances. But M. de Bort

is disposed to regard the dark markings, in which the red spot would be included, probably, as the real surface of Jupiter, seen through an unobscured atmosphere, and the position of the belts on Jupiter is thought to support the suggestions of the author. But we doubt whether astronomers are agreed that the dark markings represent clear sky, and the lighter portions cloudy vapour. Mars would seem to be the one planet in which we might expect to find atmospheric conditions similar to those here prevalent; but we are told that there are "probabilities based upon scientific reasons, that the clouds upon Mars are not distributed in the same manner as upon the earth." Though when we consider what a presumably comparatively unimportant factor the solar heat is upon Jupiter, and that, moreover, the axis of rotation is nearly perpendicular to the plane of the orbit, on a superficial view, this observation seems to be more applicable to Jupiter than to Mars. From the remark with which the paper closes, we gather that the author intends to prosecute this subject of investigation on the planets. We wish him success.

Of the second work mentioned at the head of this notice, it is rather difficult to speak. Although the author has not sketched the plan and scope of the work in any introductory chapter, it is easy to understand the principle that has guided him in the construction of the book. He has evidently been at great pains to bring together all that is valuable, or that he thought valuable, in the descriptions that have been given of hailstorms in the past, not only in the accompaniments of the hailstorms, or of the characteristics of the hailstones themselves, but also of the theories that various authorities have suggested to explain their occurrence. When we consider that in the case of nearly every hailstorm, some one is found to describe it, it is evident that the materials from which Mr. Russell can draw his information are very widely scattered. The list of authors quoted is a long one, and could no doubt have been made much longer, did not the reiteration of the same facts become wearisome. Having collected his information, the author has attempted to digest it, and has given us a summary of the characteristics of hailstones with a graphic description of the development of a hailstorm. One consequence of this method of dealing with the subject is that about three-fourths of the book consist of extracts from various authors, and only the remainder is original matter. This class of work, if not very brilliant, is, no doubt, valuable; and inasmuch as most of the extracts are given in the words of the author, with distinct references to the sources from which they are taken, this book may save much searching of original authorities, and a proportionate saving of time. Whether the materials are arranged in the most advantageous manner, is a question about which some doubt may be entertained. It would seem sometimes as though the extracts had been printed in the order in which they had been encountered, without any attempt at arrangement at all. To take the first chapter, "descriptions of hailstorms and hailstones," at first sight it would look as though some chronological order was to be maintained, for we begin in 1680, and pass next to the early years of this century; but when we get into the middle of the century, we flounder about from 1890 to 1870, and back again, without any guide. Neither is locality any rule, for we are taken all over the world, without method or system. Nor is it easy to trace any gradual scientific progress in the descriptions. We have simply more or less complete descriptions of some fifty hailstorms, or of the salient features that distinguished them.

The second chapter gives us observations of temperature, clouds, and winds at great altitudes, principally confined to the accounts of balloon ascents. In this chapter, which is very short, there might have been found room to discuss in more detail the observations made at some of the meteorological stations at considerable altitudes. The results obtained at Pike's Peak, Colorado, would seem to be of the highest importance in this connection; but the author prefers to drop this topic, though apparently germane to his subject, in order to discuss, or rather to collect, the opinions and observations of those meteorologists who have noticed the connection of electricity with the occurrence and formation of hail.

The chapter on theories of hail is interesting. In it is given the opinions of most of those whose opinions are worth recording, but in the popular and not the scientific language which some of the authorities quoted would have used. Von Bezold especially suffers from inadequate description, and, if we are not mistaken, Hertz's name is not mentioned. It would seem almost as though the author were not acquainted with much of the hydrodynamical analysis that has been applied to the atmosphere, or being acquainted with it, disapproves of its application to the present inquiry.

In the chapter on the development of a hailstorm, objection will probably be taken to the insistance and stress that is laid upon the part played in the mixture of air of different temperatures, as a primary cause in producing precipitation, whether it be of hail or any other form of moisture. The numerical example worked out to illustrate the author's point is not very clearly expressed; and even granting the figures of the author, he is obliged to fortify his case by a continual mixture. But the continual mixture would tend to produce uniformity of temperature, and disturb the accuracy of the original calculations. Undoubtedly we have present, in what it is usual to call the hail stadium, an amount of dry air which it is convenient to separate, in theory at least, from the saturated vapour also present, the drops of water, and the particles of ice or snow which probably constitute the germ of the large hailstones, and then, if the conditions are favourable, we get hail; and it is difficult to see that our author has carried the explanation much further. Nor possibly does the application of the mechanical theory of heat, however legitimate its methods may be, advance our knowledge very materially, at least in a practical direction. The local, and often confined, area over which hailstorms occur, is a marked feature of their occurrence, and is likely, for a long time to come, to baffle the applications of a general theory, and prevent any sufficient precautions being taken against the damage they produce, which it may be supposed is the practical outcome that sufferers hope to derive from the studies and inquiries of meteorological observers.

In the final chapter, headed "Conclusions," there is an attempt to gather up the results of the observations recorded in the previous chapters. It is a pretty fair

record of our general knowledge of the subject, exhibiting a tolerably complete grip of all the circumstances attending these phenomena. It does not show much originality, perhaps, but it does show very extensive reading, accurate observation, and power of condensation.

The third book mentioned is scarcely of the kind that compels one to sit down and read off-hand. It is precisely what it professes to be—a collection of the many weather proverbs which possibly the wit of one, rather than the wisdom of many, has perpetuated. If these adages did contain the results of long-sustained and well-directed observation of the habits of birds, animals, and insects, they would possess a distinct value, though it is difficult to see how the information so gleaned could indicate the severity or the mildness of the coming season; but it is to be feared they too frequently record the opinion of one who is capable of a jingling rhyme, or of one whom his comrades consider to be wise in such matters.

There are also quotations from the poets, ancient as well as modern, and all bearing on the subject of weather prediction. The hope of the author is that the perusal of such a collection may induce students to take more intelligent notice of meteorological conditions, and to avail themselves of accurate instrumental means, rather than to rely upon hackneyed quotations. A somewhat similar collection of "wise saws" was published by the United States Signal Service, but we fail to see any reference to this work in Mr. Inwards's introduction. A study of these sayings would probably furnish some additional quotations, and as the compiler aims at greater completeness in the next edition, we would refer him to this source. The book is well printed and admirably "got up," and will no doubt be welcome to many interested in folk and weather lore.

PHYSICO-CHEMICAL MEASUREMENTS.

Hand- und Hilfsbuch zür Ausführung physiko-chemischer Messungen. Von W. Ostwald. (Leipzig: W. Engelmann, 1893.)

THIS manual must be regarded as the only guide to measurements in physical chemistry which has yet been published. The book is not intended to completely cover this field of investigation, but has evidently been devised with the primary object of assisting Prof. Ostwald in his course of instruction at Leipzig. It is not an introduction to the subject, as the detail supplied, both in connection with apparatus and methods, is insufficient for the requirements of the beginner; nor is it a treatise wherein a representative collection of methods may be consulted. The book is rather to be viewed as an aid to the teacher, or as indicating to the chemist or the physicist methods which for the most part the author has found to be of service in his own laboratory.

The information contained in the opening portion of the volume is of the kind usually met with in a physical text-book: modes of calculating results, the influence of errors, the use of corrections, the measurement of length, the balance and weighing, and the measurement and regulation of temperature. Succeeding chapters take up the more common operations in glass-working, the measurement of pressure, the measurement of the volume and density of solids and liquids, and the ordinary methods of measuring vapour density. Here it may be noted that Perkin's modification of Sprengel's pyknometer, which is perhaps the most useful of all the various patterns, is not included among those described. Kopp's pyknometer also is rendered more serviceable if a short mm. scale instead of a single mark be etched on the neck.

The thermal properties of liquids are next briefly considered. Modes of determining expansion and molecular volume at the boiling-point are given with a moderate amount of detail. The determination of the boiling-point itself is, however, described in the most meagre way. Of the various methods of measuring vapour pressure the dynamical process introduced by Ramsay and Young alone finds a place. Critical temperature and critical pressure are determined in separate pieces of apparatus in the manner recently described by Altschul. No general method is indicated whereby the relation between pressure and volume may be determined under varying conditions of temperature, and no practical method can thus be given for estimating critical volume, although the principle of the new method due to Mathias is mentioned.

Calorimetry is now dealt with, and short accounts are given of the simpler methods of estimating specific heat and the thermal changes accompanying vaporisation, dissolution, combustion, and reactions in dilute solution.

Descriptions of optical measurements relating to refractive indices, spectroscopy including spectrum photometry, calorimetry, and rotatory polarisation are now introduced, and are followed by a chapter on viscosity and surface tension. In connection with viscosity, the apparatus represented is only adapted for obtaining relative values, and is quite unsuited for investigating the effect of temperature. What appears to be the correct value of the kinetic energy correction used in calculating viscosity coefficients is ascribed to Finkener and Wilberforce, whereas the first published account of the mode of deducing it is due to Couette. None of the methods given for measuring surface tension are free from the objection that air is in contact with the liquid surface.

The remaining chapters are devoted to measurements on solutions. Methods of estimating the solubility of solids, liquids, and gases, and of determining molecular weights from the freezing-points and boiling-points of solutions are given at considerable length. At still greater length, and thus in marked contrast with the treatment elsewhere, electrical measurements are next set out. Here are found accounts of the methods of measuring electromotive force and conductivity, dissociation constants, the basicity of acids, &c. The last chapter takes up elementary problems in chemical dynamics relating to the velocity of chemical change, the catalysis of methyl acetate and the inversion of cane-sugar by dilute acids being given as examples.

From what has been said it is evident that the operations dealt with in the book are only such as are frequently performed, or which at the present time are considered to be of importance. Some of these even are

occasionally omitted; no mention is made, for example, of the ordinary methods of obtaining melting-points.

It is noteworthy also that processes relating to the purification of substances for physical study are not touched upon. Accounts of the best systems of fractionation, either by distillation or crystallisation, or of distillation under reduced pressure, &c., have, it seems to us, a better right to a place in a book of this kind than, say, the chapter on glass-blowing. Again, no particular notice is taken of methods which have to be used when only a small quantity of material is available. It frequently happens that a substance can only be obtained sufficiently pure in but small quantity, and if methods of obtaining boiling-point, density, refractive index, &c. in such cases were more widely known, physical constants would no doubt be more generally estimated in the course of ordinary chemical investigations.

It is needless to state that the book is full of useful hints both on methods and apparatus, and will be indispensable to those for whom it is specially designed. It is also worthy of special recognition as being yet another effort on the part of Prof. Ostwald to place physical chemistry on a level with other departments of experimental investigation. J. W. RODGER.

OUR BOOK SHELF.

Handbook of British Hepaticæ. By M. C. Cooke, M.A., LL.D. 1 vol. 8vo. 310 pp. 7 plates. 200 woodcuts. (London: W. H. Allen and Co., 1894.)

PROBABLY no group in the British flora has received so little attention as the Hepaticæ. This is due partly to the ordinary botanical text-books describing merely the life history of the ubiquitous *Marchantia polymorpha*, and ignoring or passing over with but scanty reference the foliaceous group. But chiefly is it due to the want of a handbook by which beginners could identify their plants and obtain references to the literature of the subject. Sir W. J. Hooker's magnificent monograph, which appeared in 1816, contained plates with copious descriptions of all the British species then known; but it is now scarce, costly, and having all the species described under one generic name, *Jungermannia*, it becomes necessary, after identifying a plant by it, to refer to some other source to ascertain the now accepted name. Hooker's "English Flora," vol. v., in dealing with the same group, divides the frondose group into several genera, but retains the generic name of *Jungermannia* for the whole of the foliaceous group.

In 1865 Dr. M. C. Cooke published, as a supplement to *Science Gossip*, a catalogue with outline figures of all the British species. This is now out of print. Since then notes scattered through various journals have formed the whole of the British literature upon the subject, except the commencement of a monograph by the late Dr. B. Carrington.

Dr. M. C. Cooke has now filled up the gap by producing a "Handbook of the British Hepaticæ," containing full descriptions of all the species, about two hundred in number, known to inhabit the British Islands. The volume opens with an introduction of 20 pp., describing the position, structure, reproduction, and subdivisions of the group. This is followed by a detailed account of the species, each arranged upon the same plan. First come the diagnostic characters, followed by copious synonymy, then the habitat, and finally a full description. Each species is also represented by an outline figure, either in the text or in one of the seven plates at the end of the volume. A bibliography and index complete the work. The size and clearness of the type will be appreciated by those who use the book, as it should be, in conjunction with microscopical examination of specimens. Altogether a very useful work has been produced, which ought to fill a gap already too long vacant. C. H. W.

The Royal Natural History. Edited by Richard Lydekker. Parts 1 and 2. (London: Frederick Warne and Co., 1893.)

YET another "Natural History." There is certainly a demand for such, and without doubt there is a supply. The work is to be in six volumes, and the parts, published monthly, will complete the series in three years. The paper and typography leave nothing to be desired. The illustrations are in almost every instance, so far as our knowledge of the published parts goes, excellent; many of them are as artistic as they are accurate; and when we add that the editor of the series is an able and well-known zoologist, there can be no doubt but that the reader or purchaser will get full value for their expenditure of time or money.

In noticing a work of this nature, when the facts are as above stated, there is but little room for criticism, and despite the shock which the first blazing sound of its advent conveyed to our senses, despite the fact that "it is not compiled or translated from foreign sources," and that "the co-operation of the Bibliographic Institutes of Leipsic and Vienna" has been secured so as to obtain "all that is best and newest among the productions of the greatest natural history publishers of Europe," we yet most heartily recommend the work to all our readers, and we anticipate that most of those who take any interest in zoology will place it on their book shelves.

Of the six volumes, as was to be expected in a work of this kind, the larger number (five) is to be devoted to the backboned animals, and but one to the boneless crew; and of the first five volumes, two and a half will relate to the mammals, one and a half to the birds, and but one to the reptiles, amphibians, and fish. It is not at all a fair division, but then the mammals are thought to be the most generally interesting class, and we are promised a lot of information about "the larger game." The first two parts are devoted to the monkeys, and we have an account of nearly all the known species, accompanied with an immense number of illustrations. One suggestion occurred to us while reading over the account of the habits of the baboons; that when plants are referred to they should, when their scientific names are used, be quoted specifically as well as generically; thus a "very remarkable kind of West African plant" is mentioned as the "welwitschia," but the editor would never think of quoting the Anubis baboon as the "cynocephalus." We hope it will be a long time before *Welwitschia mirabilis* will be exterminated by the baboons. From a natural history stand-point there is really no such plant as an "*ixia*," but there are several species of the genus Ixia, upon the bulbous stems of which it would appear these baboons feed.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Origin of Lake Basins.

I WELCOME the criticism of my article on the glacial origin of a certain class of lakes by an experienced geologist like Mr. Oldham, because it probably embodies the strongest argument that can be adduced on the other side—at all events as regards

the one aspect of the problem which he alone touches upon. He urges that my paper contains a fallacy and a misrepresentation. The alleged fallacy is, that because the lakes in question are found in glaciated and not in otherwise similar non-glaciated regions, "therefore the rock-basins in which the lakes lie were excavated by glaciers." But this is not my argument, and therefore not my fallacy, What I say is—"there must be *some* causal connection between glaciation and these special types of lakes. What the connection is we shall enquire later on." That there is a "causal connection" Mr. Oldham asserts as strongly as I do myself, though it is a different, and as I have endeavoured to show, an untenable one.

This brings us to the alleged misrepresentation, which is, that I have imputed to the opponents of the ice-erosion theory, the view that the earth movements which, as they allege, produced the lakes, occurred in the period just before the ice-age came on. Mr. Oldham says, this is an unreasonable and unfounded limitation, since the movements in question probably occurred throughout the glacial period itself. I quite admit the validity of this criticism, and that I should have added, "or during the glacial period itself," to, "immediately before" it. I certainly had this probability in my mind, and the reason I did not express it was twofold. In the first place, all the advocates of the earth-movement theory appeared to assume, either directly or implicitly, the preglacial origin of the lakes; and secondly, this assumption gave them the strongest argument against my views, and I therefore gave them the benefit of it. Mr. Oldham appears to have overlooked this. Yet it is clear that the shorter you make the time since the formation of lake basins by earth-movements the more difficulty there is in explaining the total absence of valley-lakes from all the non-glaciated mountain regions of the world, since there is less time for them to have been all silted up. When arguing this point I said—in the passage evidently referred to by Mr. Oldham—"The only way to get over the difficulty is to suppose that earth-movements of this nature occurred only at that one period, just before the ice-age came on, and the lakes produced by them in all other regions have since been filled up." I thus gave my opponents the benefit of an extreme supposition which was all against myself; while the more reasonable view, that earth-movements are just as likely to have occurred during and since the glacial epoch as before it, renders my argument from the geographical distribution of lakes much stronger, since it is impossible to believe that, if lake basins as large and as deep as those of Geneva, Maggiore, Como, Constance, and Garda, were formed in non-glaciated regions as recently as the middle or latter part of the glacial epoch, a considerable number of them would not be still in existence.

Of course, if it can be shown that filled up lake-basins exist in tropical and subtropical regions, corresponding in number, position, size, and depth, with those of glaciated areas, the argument from geographical distribution will break down. At present I am not aware of any evidence that such is the case. But even if it were so, there remains the singular correlation between the size and depth of lake basins and the known size of the glaciers that occupied these valleys; together with the surface and bottom contours of the lakes themselves, so strongly opposed to their production by any form of valley-subsidence or earth-movements.

A friend has pointed out an unsound argument in my article on the above subject in the *Fortnightly Review*, and I therefore ask to be allowed to state what it is, and thus avoid its being possibly made the subject of discussion in the pages of NATURE. As a proof of the very great erosive power of ice I have adduced Dr. Helland's estimate of the quantity of Scandinavian *débris* in Northern Europe. But it is evident that this only proves the great carrying power of the ice, since the rock and gravel would be mostly of sub-aerial origin. It, however, indicates a very long period during which the ice-sheet was at work, while the clayey element in it would be due to erosion. The larger part of this, however, would certainly have been carried away into the North Sea during the passage of the ice-sheet across the Baltic. The enormous quantity of boulder-clay in North America, which I have also referred to, is a better indication of true ice-erosion.

ALFRED R. WALLACE.

THE question you have allowed me to raise is too important and far reaching to justify its dissipation upon personal issues. It cannot be thought unreasonable that those geologists who propound transcendental theories should justify the mechanical postulates on which they claim to base them. This is all I have asked.

Dr. Wallace asks me to explain what will happen when sufficient pressure is applied to ice not only to crush it, but to induce regelation. I have already explained in my work, that the notion of fracture and regelation taking place in glaciers is at issue with the details of their differential motion as tested by experiment. There is no evidence that ice which on pressure being applied to it has ample room to move, will undergo regelation at all. The pressure when crushing ensues will be dissipated in the direction of least resistance, and most probably upwards. This emphasises Mr. Deeley's statement, and he wrote as a champion of Dr. Wallace, that "fracture and regelation have little to do with the question."

Dr. Wallace then returns to his charge against me that I have in some way committed myself in my work to a position inconsistent with the one I am now maintaining. I can assure him that if he has read this meaning into my words, it was not what they were meant to convey. In giving the history of the "Glacial Nightmare," I entered largely into the views of Charpentier, and in so far as he championed glaciers as against ice sheets I agree with him. I have said that his views "*are for the most part sound and unanswerable*, since *they finally established for the Alpine country and for Switzerland the fact that glaciers were formerly much more extensive*," &c. Beyond this I could not go, since my work was written to prove the unscientific character of the extravagant conclusions of the later glacialists, including Charpentier himself after he became a follower of Agassiz. Apart from this, however, what your readers I am sure would welcome would be an *argumentum ad rem*, and not one *ad hominem*.

In demanding that the advocates of the glacial theory in its extravagant form should justify their premises and postulates, I must not be understood to decline to meet the geological case against the glacial excavation of lobes. I have met it at great length already in my recent work, but not so ably and not so thoroughly as Mr. Spencer met it in his elaborate and crushing examination of the critical case of the North American lakes, which I commend most heartily to the study of enthusiastic champions of omnipotent ice.

The geological question, however, is necessarily contingent upon the mechanical question, and no amount of ingenuity will in the long run enable those who invoke ice as the author of all kinds of geological work to evade the duty of proving its capacity to do that work, and notably to explain how it can travel over hundreds of miles of level country, or suddenly begin to excavate deep and extensive lake basins after it has been moving gently over its own bed of soft materials for many miles, or, indeed, how it can excavate on level ground at all. The first step is to show that ice can convey thrust in a way to compass these ends; the second one is to show whence this thrust is to be derived. Your readers who are committed to no theories unsupported by facts, will not quarrel with the reasonable demand that these first steps should be surmounted before we advance any further. Those who like to traverse cloud-land on the wings of fancy may be otherwise satisfied. To them I would only say that the result cannot be science; it must remain nothing more than poetry.

HENRY H. HOWORTH.

30 Collingham Place, Earls Court, December 30, 1893.

Hindoo Dwarfs.

IN your issue of November 9, 1893, is a notice of some photographs, by Colonel A. T. Fraser, of two dwarfs, taken in the Kurnool district of the Madras Presidency, near Bellary. From the account given of these dwarfs—the hereditary nature of the deformity, its limitation to the males of the family, the inability to walk, the normal bodily growth up to six years of age—it seems possible, if not probable, that the family is afflicted with the disease known as pseudo-hypertrophic paralysis (Duchenne's paralysis). Any physician could settle the question immediately on seeing one of the subjects in question; and very probably a study of the photographs would be sufficient. I have had cases of this disease in my wards at the General Hospital, sent from Bellary. Perhaps Colonel Fraser would kindly send me a copy of one of the photographs, or show them to another medical officer, and tell us his opinion.

A. E. GRANT.

Madras, December 2, 1893.

EWART'S INVESTIGATIONS ON ELECTRIC FISHES.[1]

THIS is a magnificent memoir containing the very interesting observations of Prof. Ewart concerning some of the most important chapters of comparative anatomy. Everyone who has an idea of the enormous difficulties connected with these investigations will admire the great skill and successful perseverance with which the author has followed up many dark problems and thrown light upon a number of the most obscure questions.

My studies have been in the same direction for nearly twenty years, and I congratulate my companion in work upon his great success.

It might appear a bold attempt for a foreigner to debate the complicated problems treated in the work; but, on the other hand, there is apparently a strong interest attached to the endeavour to enlarge the field of international intercourse, and this will serve as an excuse for any awkwardness of language.

There is no doubt that science is the chapter of knowledge most entitled to international treatment, and Prof. Ewart himself has done his best to acknowledge the merits of foreign authors. Still, I wonder whether he is aware of the fact that in many places his deductions bear a more or less national character. The proof of that fact cannot be compressed in a few notes, but it may suffice to point out the places where the differences of treating these matters between British and continental writers seem to be most apparent.

Everybody will probably agree that the whole of Prof. Ewart's work deserves very high praise. The plates, which have been accurately drawn by the author himself, are beautifully printed, and yield very ample and useful instruction to anyone who wants anatomical and histological information about these interesting, and yet very imperfectly known, organs. They give a clear account of the immense work the author had to accomplish before he could give so exact and complete representations of the electric organs as well as the cranial nerves and the sense organs.

It will remain to Ewart's undisputed credit that he has brought before the public a large amount of information on the anatomy and histology concerned. The explanation of the plates facilitates the understanding of them, and forms the connecting link between the figures and the tenour of the deductions. It is proved by comparing a great number of organs in different species of Raja, that there are two distinct kinds of electric organs, viz. "cup-shaped," which occurred in *R. circularis*, *radiata* and *fullonica* of the British seas, in *R. eglanteria* from abroad, and, on the other hand, "disc-shaped," which he found in *R. batis*, *macrorhynchus*, *alba*, *oxychynchus*, *maculata*, *clavata*, and *microocellata*.

Everywhere Ewart confirms the statement of former writers, that the electric organs were derived from muscles of the tail which became changed into electric tissue. With great care and skill he has followed the development of these organs in the embryo, and showed how the muscles gave up their firm hold on the sinews, and shrivelled up to discs or cups.

There remains yet one difficulty to be overcome, which the author has not considered; that is to say, he finds the termination of the nerves for each element at the proximal *end* of each muscular club, and compares them (as other authors do) to the motor end plates of common muscles, which are fixed alongside the striped fibres, and not at the end.

That is, of course, a subordinate question, and I am very glad to repeat here what I have stated in former publications of mine, that the muscular origin of the electric organ in the skate also appears beyond doubt, and that I thoroughly agree with Prof. Ewart, not only in that principal question, but also in his deductions regarding the phylogenetic development.

One of the general deductions appears rather strange, not only to me, but to most authors on the continent interested in the matter. How is it possible to consider the electric organs of the skate as such of "vestigial character" before any evidence is given in favour of a retrograde development, which takes place at any period of life? Are not all the statements of Ewart, as well as of former authors, clear proofs that the development is progressive, or at least resting at a certain degree of perfection, after having left the starting-point (muscular tissue) only for a comparatively short distance?

The organs might still advance to further perfection (which I presume they do), or they might become rudimentary again; but so long as there is only progressive and no retrograde motion in the development, it is hardly worth while to argue about the probability of their vestigial character.

I differ only so far from Ewart, as he does not convince me that the electric organs of the skate are as equally perfect as the organs of the Torpedo. In the skate, and up to a certain degree also in Mormyrus, the striated layer of the organ is histologically and optically (in polarised light) proved to be the rest of the original muscular tissue. If there is so much left of the former state of things, it proves, in my opinion, that the process of transformation going on is not so far perfected as in another case (Torpedo), where nothing of the muscular character is left.

I may be permitted to quote here a suggestion I made in a former number of this journal (January 19, 1893) regarding the probable way of phylogenetic development in these organs. It seems to me possible that a kind of physiological alteration changes certain muscles so gradually into electric tissue that a comparatively still imperfect element under favourable circumstances might give an electric shock, which proves useful to the skate for maiming small animals upon which it preys; and so the fish might continue to improve the organ by using it.

Ewart (*R. circularis*, p. 546) argues exactly in the same way as I did, but hesitates to assume that weak electric shocks might be of any use to the skate. It should be kept in mind that small aquatic animals are often extremely sensitive to electricity, and that an unexpected weak electric shock startles even a human individual. At another place, where the author treats the same theory, and grants the possibility of all the other presumptions, he holds back from the universally accepted principle, that constant use makes an organ increase. (Skate, p. 411).

Of course, up to a certain degree, the phylogenetic development of the electric organs contains still a good deal of mystery, and will, I fear, always lack the scientific proof so eagerly looked for; but I must repeat my conviction, that it is easier to imagine the transformation of striped muscle in electric tissue, than to explain by natural selection the development of any distinct, lively-coloured pattern on the wing of an insect.

The cautiousness of the author is, however, to be praised, and it is very interesting to follow his arguments about the *pro et contra* in these complicated matters.

I cannot admire as much another chapter of his paper, where Prof. Ewart does not seem to be quite up to the international mark; it is that in which he compares the number of electric elements in the different electric fishes. (Skate, p. 397). The total of electric elements for each organ in *Torpedo marmorata* he gives as 250,000, and in spite of the great difference of this number with the sum found by other writers before Ewart, he does not say one

[1] "Electrical and Lateral Sense Organs, and on the Cranial Nerves of Elasmobranchs." By Prof. J. C. Ewart. (Edinburgh, 1893.)

word about that divergence. I spent much time in counting the elements in the organ of Torpedo, and confirmed my results by counting also the ganglionic cells belonging to the plates. My total comes very near to that of Valentin, but amounts only to 179,625 in each organ.

Prof. Ewart cannot expect me to give up my number in favour of his, published much later, before he proves that I made a wrong estimate. He speaks also of the large Torpedo of America, and calls it *Torpedo gigantea*. It seems he is not aware of the fact that the name of *Torpedo gigantea* is given to the petrified species from the Monte Bolca, whilst the American species got the name of *T. occidentalis* (Storer). He ignores, or neglects, at the same time, the fact that a near related species, which has about the same number of electric elements, generally named *T. nobiliana* (Bonap.), occurs also in the British seas.

If it is difficult to explain such want of harmony with other authors; it amounts to an impossibility for a foreigner to give a clear account of the following papers concerning the cranial nerves of Elasmobranch fishes. Not that I mean to blame my learned colleague for this; on the contrary, I admire the papers very much, and recommend them with all my heart to everyone who wants instruction about the finer details of these nerves; but with regard to the nomenclature employed. I am afraid very few continental authors will agree with the homologies stated by Ewart. When he in a certain place says against Sappey, "that nerve is all but universally acknowledged to be a part of the facial," Sappey will most decidedly state "that nerve is all but universally acknowledged to be a part of the trigeminal."

Considering it of little use to discuss the confusion of names in the papers quoted by Ewart, I wish it to be borne in mind that the leading principle of the author to prove his homologies is the equality of distribution of the nerves in the peripheric organs. If that holds good, as I am convinced it does, how can he at the same time give the name of a true motor nerve (*N. facialis*) to a cephalic nerve of a true sensitive character? Perhaps he will answer, "All, or at least most, of the other authors do, why shouldn't I do the same?" Putting aside the protest many continental authors (myself included) make against such nomenclature, at any rate his principle of innervation is given up, and I am firmly convinced that the comedy of errors in the nomination of cranial nerves in comparative anatomy will not cease until quite new names or, perhaps still better, only numbers are applied to them according to the place of origin in the substance of the central nervous system. Motor and sensitive nerves must be kept separated by all means, segmental and not segmental nerves may be designated at the same time in any proper way.

It is in this respect that the want of an international understanding is most severely felt, and we must hope that the future may provide an advancement of science also in the matter; for before a firm and clear base for these homologies of nerves is given, we might just as well talk Chinese toge her.

Professor Ewart's investigations about the cranial nerves had for their chief purpose a clearer insight into the innervation of certain organs of sense, treated in another paper annexed to the same volume. I am very glad to state that the impossibility of accepting his homologies does not interfere with his results as regards the innervation of these sense organs.

The anatomical skill of the author is best shown in the treatment of the structure of these organs. So far as my own experience in these matters goes, I am led to ask, Are his statements and figures of the sensory canals and the nerves belonging to them very correct and complete? He overreaches the previous writers treating the same objects by the admirable finish of his papers which, as far as I see, ought to be followed by another concerning the ampullary canals.

In this chapter I have also to object to his way of treating the literature and of stating homologies in spite of his own principles.

The sense organs I discovered on the skin of Raja, and called "Spaltpapillen," named "pit-organs" by Ewart, were not found by any other author before. It is not true that Merkel saw them on the back of Mustelus and at the mouth of Spatina; he described only "freie Nervenhûgel" (*free* nervous collines) in these places. The name itself proves that the sense organs described by Merkel belong to another group altogether, and so does their position.

How Ewart, who places such importance in the distribution of the nerves, can find that the "Spaltpapillen" probably correspond to organs of Squatina placed at the mouth of a very different make and different innervation, he may know himself, but the reader finds it impossible to follow such argument.

The figure he gives of the pit-organ (sensory canals, pl. 3, Fig. 10) does not show such an organ fully developed. Otherwise the split would be narrow and straight, the cells by which it is lined flattened and columnar, not rounded, the papilla itself much higher raised above the surface of the epithelium, and pigment cells frequently found between the epithelial cells. (Comp. my paper: "Uber Bau und Bedeutung der Canalsysteme unter der Haut der Selachier." *Sitz. Ber. d. Berlin Akad. d. Wischenss*, 1888, s. 291.)

The papilla is, in the adult, a good deal raised above the level of the skin, so that even the sense organ at the bottom of the split in the papilla has still a somewhat elevated position. This position prevents me from admiring the name of "pit-organs," as a pit ought to mark a depression below the main level. Continental writers will also shake their heads in reading that a differentiated group of epithelial cells forming a sense organ, and resting between them, is called a "follicle," which by all means wants a kind of stronger envelope enclosing the cells. But I quite agree that in England Latin words might be admitted, which would not do on the continent.

Before Prof. Ewart proceeds to describe the ampullary canals, I recommend him once more to study the paper of Savi concerning these canals. He places the French author amongst those who take also the ampullary canals for sense organs, which is a great mistake, as Savi affirms in most decided terms the excretoric function of the ampullary canals. (Mateucci et Savi, "Études Anatomiques sur le Système Nerveux et sur l'Organe Electrique de la Torpille," p. 331.)

But such objections very slightly detract from the great merit of the author. They only prove the strong interest which the perusal of Prof. Ewart's papers has aroused in me, as it will do in all other readers. I cannot conclude my remarks without acknowledging once more, with all my heart, the magnificent results obtained by him, and I trust that he may succeed further in the same direction. GUSTAV FRITSCH.

NAVIGATION BY SEMI-AZIMUTHS.[1]

THE year 1893 should be an interesting one to nautical men. A new Daniel has come to judgment in the person of Mr. Ernest Wentworth Buller, M.R.A.I., M.R.U.S.I., M.I.E.E., the inventor of the semi-azimuth system of navigation, who is equally earnest in denouncing the shortcomings of the existing systems of

[1] "Semi-Azimuths. New Method of Navigation, being a combination of Spherical Trigonometry and Mercator's Sailing." (London: Norie and Wilson, 1893.)

navigation, and in advocating the merits of his own. For the precise object of the new method let our author speak for himself. In page iv. of the preface we read: "It is here claimed for the semi-azimuth method that it renders double altitudes unnecessary; that a better result than they have been supposed to yield can be obtained from *either observation* singly, and this also with a great saving of time and trouble."

Again on page 27: "The range of the General Method extends, either from the meridian, or from the limit at which the direct method becomes uncertain, viz., three points from the meridian, up to an azimuth of seven points, or more, that is to say to within less than one point from the prime vertical, which may be considered the practical limit of the semi-azimuth method. . . . It may safely be affirmed that nothing like this extent of range in the computation of latitude has ever been attained by the current systems of navigation."

The feats which our new teacher claims to have accomplished are two in number.

(1) The discovery of a new formula for reduction to the meridian.

(2) By a somewhat tedious system of approximations to obtain by the semi-azimuth method from either of two observations for double altitude the same or a better result than would under the usual double altitude method be derived from the two combined, subject only to the limitation that the body must not be within a point of azimuth from the prime vertical.

Let us consider (1) and (2) in detail.

First with regard to (1), the formula obtained is this:

$$\text{Reduction} = h \cos l \times \text{arc } \tfrac{1}{2} \text{ azimuth}.$$

The formula is a simple one, and now that hour angle is so easily converted into azimuth by the Burdwood and Davis' tables, there seems no objection to its adoption by those who prefer to work out their correction rather than to take it direct from the tables.

Mr. Buller deduces the formula from a somewhat elaborate construction on the Mercator's chart. It is, however, merely an old friend masquerading in a new dress, and he might, if he pleased, have easily obtained it from the expression in ordinary use.

Thus in the formula

$$\sin\frac{\theta}{2} = \sin p \sin c \operatorname{cosec} z \sin^2\frac{h}{2},$$

where θ is the correction, p the polar distance, c the colatitude, z the zenith distance, and h the hour angle, if we assume that

$$\frac{\sin\frac{h}{2}}{\sin\frac{A}{2}} = \frac{\sin h}{\sin A} = \frac{\sin z}{\sin p},$$

where A is the azimuth, we obtain

$$\sin\frac{\theta}{2} = \sin c \sin\frac{h}{2} \sin\frac{A}{2},$$

or

$$\theta = \tfrac{1}{2} \sin c \,.\, h \,.\, A \,.\, \sin 1',$$

the Buller formula in a logarithmic shape.

The use of this formula is first exemplified by its application to examples from Jeans' "Navigation," and so long as the azimuth is small it answers well enough. But our author is tempted further afield, and so soon as he gets well away from the meridian his formula begins to give trouble, and he is only able to obtain an accurate result by a process of approximation so cumbrous as to be quite useless for practical purposes. As an instance of this, witness the example of which the results, but not the full work, are shown on p. 14. Were the work to be shown in full, it would occupy more nearly two pages than one page of the text.

Now let us suppose it had not been given to Mr. Buller to discover the methods lately presented to the nautical world, and that he had been content to follow mere ordinary processes.

Imagine, for instance, that he had selected the well-known furmula

$$\text{vers Mer Zen Dist} = \text{vers } z - \sin p \sin c \text{ vers } h$$

in order to work out example § 16, p. 12.

Then, upon his own assumption that the latitude was 51°, or 12′ in error, he would obtain as a first result lat. 50° 49′ 42″. Repeating the process with this new latitude, a second approximation would be 50° 48′ 16″, while a third repetition would result in 50° 48′ 3″, the true value and this with less than one-third of the trouble.

The semi-azimuth had better, therefore, be confined to observations within a point or so of the meridian.

We pass on to the second and more important part of the task which Mr. Buller has set himself, namely, to show that the latitude within certain wide limits of azimuth may be obtained with accuracy from a single altitude without waiting for a second.

And this may be at once conceded, that by making the necessary adjustments for change of azimuth, and by successive approximations, an altitude may be reduced to the meridian, even when the azimuth is considerable.

But the same result may be obtained from the versine formula given above with far less trouble but greater accuracy.

The question, then, narrows itself to this: Why should we not in all cases of observation within seven points of the meridian, reduce the altitude to the meridian at once, by one method or another, and so obtain the latitude without waiting for hours to take a second altitude, and then making lengthy calculations?

Why have Robertson, and Raper, and Inman, and the other giants failed to hit the bull's-eye, while it is left to Mr. Buller to put his finger on the "blind spot"?

The answer is easily stated.

The "blind spot" is to be found not in the accepted custom of mariners, but in the author himself. Mr. Buller in arriving at his conclusions leaves out of consideration the real vital point which attaches to every observation taken ashore or at sea, but especially to the latter class, namely, what is well defined by Raper as the "Degree of dependence" to be placed on the observation.

In every observation off the meridian we have to deal in one form or another with a spherical triangle, in which three elements being given we have to find a fourth.

Now the three given elements are in general known only approximately, and it behoves us to find under what conditions an observation should be taken that the smallest possible error may be produced in the final result. In the problem under consideration, treated by the Buller process, the data are the polar distance, the approximate colatitude, and the zenith distance.

Of these the polar distance may fairly be regarded as accurately known, since the difference can only be at most but a few seconds.

The latitude is required to be known only approximately, the object of the observation being to find the amount it is in error, and it has already been admitted that the new process will suffice to obtain the correct latitude, *always supposing that the observed altitude is correct.*

What reason is there then to consider that the altitude is correct, and what will be the effect if it is incorrect?

When we take into account the haziness and uncertainty of the horizon, the difficulty of accurate observation on board a rolling ship, the varying effects of refraction, the imperfections of the sextant, and the personal error of the observer, it is probable that an average error of 2′ is a very moderate estimate.

Taking 2′, therefore, as an average value, let us see

what will be its effect upon the typical examples in the text, worked first by the new process, and secondly by the old method of double altitude.

On page 30 an example (§ 32) is taken from Lecky, which will answer the purpose.

The data are as follows. Lat DR 32° 15′ N.

March 7, 1880.		Times by chron.		Altitude.		Bearing.
		h. m. s.		° ′ ″		°
11h. a.m.	...	1 11 3·8	...	50 0 0	...	S. 25 E.
3h. p.m.	...	5 11 1·2	...	33 17 45	...	S. 57 W.

Sun's declination, 4° 59′ 15″ S. for first observation; 4° 55′ 30″ S. for second observation.

Let us suppose that an error of 2′ occurs in the second altitude, the one treated for reduction to the meridian.

The error in latitude (dl) produced by an error in altitude (dz) is given approximately by the formula

$$dl = \sec A_1 \cdot dz,$$

where A_1 is the azimuth of the body.

Thus $dl = \sec 57° \times 2'$, or 3′ 40″ nearly.

But if treated, so as to take in both observations, by the double altitude process,

$$dl = \frac{\sin A_2}{\sin (A_1 + A_2)} dz,$$

where $A_1 = 57°$, $A_2 = 25°$, the azimuths being reckoned from south in each case. Thus

$$dl = \frac{\sin 25°}{\sin 82°} 2' \text{ or } 51''.$$

So that in one case a reasonable error in altitude gives an error in latitude of nearly 4′, in the other of less than 1′.

One other instance will perhaps suffice. On page 36 an example from Riddle is worked out, wherein an error of 2′ in altitude would produce an error of 18′ upwards in latitude.

Such a result at once condemns the observation. Indeed, for the purpose of accurate determination of latitude, the double altitude stands out among the various methods a very king. In other cases, as in the meridian altitude, we are satisfied if the latitude is no more in error than the original observation. In a double altitude, taken under advantageous conditions, only a fraction of the error in altitude appears in the final result.

It is somewhat remarkable that Mr. Buller's evident appreciation of Sumner methods has not made him more familiar with the main principles which apply equally to all classes of observations.

Every observation furnishes the observer with a circle upon the globe, a straight line upon the Mercator's chart, on which to place his position. The circle has the sun's projection on the earth for its centre. The line has the sun's line of bearing perpendicular to it.

If this line of position is inclined at a very acute angle to the meridian, that is, if the body observed is near the prime vertical, it is evident that a very small increase in the perpendicular drawn from the sun to the line of position, that is, a very small increase of zenith distance, will produce relatively a very large difference of latitude. And this condition, coupled with the impossibility of obtaining accurate altitudes at sea, is sufficient to account for the restriction of ex-meridian observations to a point or two in azimuth from the meridian.

The British seaman, therefore, had better pause before he throws overboard his Norie or his Raper, and takes to his heart the new Buller methods.

The greatest self-confidence, the most implicit belief in the reality of the mission to which he has been called, will not enable Mr. Buller to find the latitude accurately by a single altitude near the prime vertical, for the very simple reason that the error (even when supposed small) which must be expected in the altitude produces a large error in the latitude, and thus vitiates the result.

If he would make the ex-meridian method available as he proposes to do, at almost any time of day, the author must supplement his treatise by the invention of some appliance for measuring altitudes very much superior to any now in use.

Pending its production the very pertinent question asked in page 36, "We have known long enough how to get a fairly correct A. T. S. from an observation near the Prime Vertical and the latitude D. R., but who has yet shown how to obtain the *True Latitude*"? must remain unanswered.

There is indeed freshness in the "New Method of Navigation," Part I., but no light. That perhaps will be supplied by Part II. G.

VOICES FROM ABROAD.

THE following literal translation of parts of an article recently published in the *Chemiker Zeitung* (Nos. 85 and 86, 1893) is an appropriate addendum to a recent article of mine in this journal. It must be sorrowfully admitted that in essential particulars the picture is a true one. HENRY E. ARMSTRONG.

"Notwithstanding the enormous industrial development of England, the appreciation of science by technical workers is inconceivably slight, the main cause being deficient comprehension. The Englishman is conservative in all his customs, in his way of living, and not less in his methods of manufacturing, so that there are still very many manufacturers who would be as little prepared to place the control of their works in the hands of a scientific chemist as to convert them into philanthropic institutions. At present great efforts are certainly being made to alter this condition of affairs by the aid of technical schools modelled on German lines, but opinions as to the value of these schools are as yet much divided; and, indeed, for various reasons their ultimate success is doubted. In the first place, it is to be borne in mind that these institutions are not under State control, but are governed and controlled by local boards. Moreover, the preliminary training which their students have received is not to be compared with that of students in the German institutions, as an education such as is given in the German Realschulen and Gymnasiums—of the character given in England at most by the grammar schools—is only procurable by those who are well off, owing to the enormously high school fees (about £20 or 400 marks a year). The possibility of consolidating and widening the technical training by a short subsequent course of scientific study at the University is absolutely out of the question in most cases, owing to its extreme costliness. It is therefore probable that these schools will but produce a number of half-educated persons who will take up positions as chemists and will thereby but bring the chemist proper into discredit.

"It is clear that under these circumstances there is but very little prospect that a chemist coming to England will find a suitable position. I cannot sufficiently strongly caution 'young chemists' against coming to England on the chance of picking up something good, even when provided with good introductions. So few analysts are in demand here that the chance of securing such a post is most uncertain. Works and laboratories in which scientific work is systematically carried on scarcely exist, not one even of the English aniline colour works having a scientific laboratory worthy of the name. The 'young chemist' has therefore very little chance of securing an appointment, as he does not possess the necessary qualification for a works post, that is to say experience,

and the volunteer nuisance is scarcely known here even by name. I can therefore only repeat that it is a very risky enterprise for a young, inexperienced chemist to come to England without a definite engagement, as so often happens. The result, with very few exceptions, is disillusionment, and many get into most unfortunate positions through financial pressure. The outlook is somewhat better for a chemist who has had experience and practice in works. But even such will find it infinitely more difficult to find posts in England than it is either in Germany or Austria, and will do well to go to England only when offered a definite appointment. The thorough scientific training and business capacity of the German chemist is unreservedly recognised by all unprejudiced judges in contradistinction to that of his English colleague. In carrying on routine operations, the English chemist is doubtless as competent as the German chemist, even if he be not his superior, but in conducting and developing chemical industries on a scientific basis the latter is far in advance of the former.

"I need refer but briefly to the great chemical industries, as they are well enough known. Of these the first to be mentioned is the soda industry, including that of sulphuric acid and chlorine; furthermore, tar-distilling, dyeing, calico-printing, the manufacture of iron, steel, copper, tin, and antimony, glass-making, the utilisation of fatty matters, the Scotch paraffin industry, and the manufacture of bichromate. These industries, excepting glass-making, employ a considerable number of chemists, although, in proportion to their output, not nearly so many as the German works. This is especially the case in dye works, calico-printing works, and in those dealing with fatty matters, many of which carry on their manufacture without chemists, or only with the aid of very imperfectly trained chemists, as every one here regards himself as a full-blown chemist who, after a most elementary preliminary training, has attended a technical course during one, or at most, two years. At least 80 per cent. of the chemists engaged in the industries mentioned are Englishmen, the remainder being either Germans or Swiss. I have never met a French chemist here. With few exceptions the condition of these industries during recent years must be characterised as dull and even as bad in some cases; they therefore offer the chemist little prospect of employment, and foreign capital is certainly not to be invested in them with advantage. Only dye-works and those utilising fatty matters offer a prospect to the experienced chemist, as these are both distinctly capable of being improved in position. The helpless condition of the English aniline colour works is peculiar, these having been simply stifled by the German works, which have developed with such giant strides. The English works eke out a miserable existence, and altogether do not employ as many chemists as are to be found in a similar German works of the fifth or sixth rank. Fuchsine, soluble blue, chrysoidine, Bismarck brown, and the few naphthol colours unprotected by patents, are almost the only colours manufactured. Not a single dyestuff of importance is made by any English firm alone, as scientific laboratories such as are a matter of course in every German works exist here only in the most rudimentary form. Most of the chemists engaged in English aniline colour works are German (??), but the demand for chemists in these works is very small. The erection of such a works in England on the German model could only be achieved by the large German firms engaged in this industry; it is another question whether it would pay. But the manufacture of pigments—of mineral colours and lakes—is certainly capable of development here. It is true there are a number of such works, but these rarely employ a chemist, and still more rarely one who has had a thorough scientific training. Consequently, enormous quantities of lakes are imported, especially for printing oil-cloths and carpets, which might equally well be manufactured on the spot. The necessary capital would be not an inconsiderable one, and may be estimated at, at least, 150,000 marks. Competent chemists in this branch can probably count on easily finding employment here.

"The manufacture of fine chemicals, which at present are almost entirely imported from Germany and France, is certainly capable of considerable development here. Of these may be mentioned especially, tannin, tartar emetic, pyrogallol, oxalic acid, cyanide of potassium, and most of the almost innumerable chemicals and preparations which are made use of in trade, and which are either not made here at all, or in altogether insufficient quantity and of poor quality. With reference to such articles, in the case of which wages form a considerable item in the cost of production, it is to be borne in mind that English wages are on the average considerably higher than German."

THE EFFECTS OF LIGHT ON THE ELECTRICAL DISCHARGE.

WHILE engaged on his classical experiments Hertz noticed that the appearance of the discharge between the two terminals of the oscillator was greatly changed upon the spark gap being illuminated by the light coming from another spark. This change was not due to an electrical action of the sparks, for it was equally well produced by other sources of light, such as the electric arc and burning magnesium, while all effect immediately ceased on interposing a plate of glass. Since the time when the above observations were made many experimentalists have investigated this subject and have obtained rather divergent results. In most cases the source of light employed has been the electric arc formed between carbon rods, though, with a view to increase the proportion of ultra-violet rays emitted, Bi hat and Blondlot used carbon rods with aluminium cores, while Righi used a zinc rod for one terminal. Other observers have used the spark of an induction coil passing between terminals of copper, zinc, or aluminium. While Hertz had only noticed that the illumination of the discharging knobs increased the facility with which sparks passed, Wiedemann, Ebert and Hallwachs found that it was only when the negative terminal was illuminated that this effect took place. More recent observations by Branly have led to this view being modified, for he finds that on illuminating a piece of zinc by the sparks of a large induction coil produced between aluminium terminals, if the source of light is sufficiently near to the plate, the loss of charge is nearly as rapid for a positive as for a negative charge. On increasing the distance between the spark and the charged plate, the decrease in the rate of loss of charge is much more rapid for positive than for negative charges, and thus at some distance from the source of light the negative charge is the only one which is appreciably affected. Hence radiation of certain kinds increases the rate at which a positively charged body loses its charge, just as in the case of a negative charge, but the rays which are active in the case of positive electricity are absorbed by even a small thickness of air, while those rays which are unabsorbed are still able to accelerate the discharge of a negatively charged body.

After having made a series of experiments in air at ordinary pressures, Stoletow on the one hand, and Righi on the other, have investigated the influence of pressure on the phenomenon, and have both found that the effect increases with a decrease of pressure, while Stoletow has shown that if the rarefaction is carried to the extreme limit there exists a pressure, after which the effect decreases as the pressure is further diminished.

An experiment of Bichat's seems to show that the loss

of electricity is due to convection currents, and this view has been further strengthened by Righi, who placed a plate of ebonite covered with tin foil on its upper side above a brass plate on which some figure, such as a cross, had been traced with varnish so that the plate was protected at these points from the effect of the illumination, the active rays being absorbed by the varnish. The negative pole of an electric machine was connected to this plate, the positive pole being connected to the tin foil, and the light of an electric arc allowed to fall on the under plate for a few seconds. The plate of ebonite being removed and powdered over with a mixture of sulphur and red lead a yellow cross on a red background was obtained of the same size as the one traced on the brass plate. As the sulphur attaches itself to those parts of the plate which are positively, and the red lead to those which are negatively charged, it follows that the parts of the lower plate which were not protected by the varnish have lost some of their negative charge, which has been carried on to the ebonite plate, and that this displacement has followed the lines of force of the electric field between the plates, which are in this case perpendicular to the two plates. This conclusion is further strengthened by observing that, if the electrified particles which escape from the lower plate are prevented, by means of a screen, from reaching the ebonite, a shadow of the screen is obtained.

The explanation that this convection is caused by the molecules of gas which, after being in contact with the body, become charged and are repelled, is hardly satisfactory, and the experiments of MM. Lénard and Wolf seem to show that it is particles of dust which carry the charge, for they suspended an insulated plate of metal in a box filled with air which had been carefully freed from dust. A plate of quartz fixed in one side of this box allowed the light from an electric arc to fall on the metal plate, while a stream of some vapour could be introduced through a side tube. Under these circumstances the vapour was condensed on allowing the light to fall on the plate if it was uncharged or negatively charged, while if the plate was positively charged no condensation took place. As it is known that a given space can become supersaturated with vapour when no dust is present, but that the introduction of the least trace of dust causes an immediate condensation, it appears that when a body either uncharged or negatively charged is illuminated it gives off some dust, and that the loss of charge is due to this dust. Further particulars of the work which has been done in this subject are given in a paper by M. Blondin in *Électricité*, p. 313, 1893. W. W.

NEOLITHIC DISCOVERIES IN BELGIUM.

THE fact that in Belgium flint was in certain districts largely worked during Neolithic times, for the manufacture of hatchets and other implements, has long been well known. The mines in the chalk near Mons, from which the rough blocks of flint were procured by the ancient flint-workers, have frequently been described, and bear a close analogy with the old workings at Grimes' Graves, near Brandon, and with the pits near that place, still being sunk by the flint-knappers of the present day. The fields in the neighbourhood of Mons have their surface strewn with roughly-chipped hatchets, and in other districts the occurrence of worked flints has been not unfrequently noted. In a memoir, recently published in the *Bulletin de la Société d'Anthropologie de Bruxelles* (Tome xi. 1892–93), M. G. Cumont has placed on record his discovery of two important Neolithic stations at Verrewinckel and Rhode-Saint-Genêse, neither of which places is far from the main road from Brussels to Charleroi, while both lie at but a short distance from the field of Waterloo. The forest of Soignes extended in early times over the whole district, and though both stations are on promontories of high land, there are or were, in the neighbourhood of each, springs or ponds from which to obtain a supply of water and, possibly, of fish.

The principal of the two was that at Rhode-Saint-Genêse, whence, including flakes and scrapers, M. Cumont has obtained no less than 3591 worked flints, a few implements made of other kinds of stone being reckoned among them; while Verrewinckel is credited with 815 specimens. Of all the forms a good summary account is given, and characteristic examples are figured in five plates. A detailed map of the district is also given. That the manufacture was carried on at the stations is proved by the presence of upwards of 240 nuclei from which flakes have been dislodged; but few of these appear to have rivalled in size those of specimens near Mons. It is indeed suggested that the hatchets and larger implements were rough-hewn at Spiennes, and finished where they were found. That this was the case is further shown by the fact that some twenty *polissoirs* were collected by M. Cumont, who also regards the flint which forms the material of the implements as having been derived from Spiennes, Obourg, or the neighbourhood of Mons. Over a hundred arrow-heads figure in the lists, and some of these, as shown in the plates, exhibit skilful workmanship. A few quaternary or palæolithic implements from the same region have been described by M. Cumont in another paper. He is to be congratulated on the rich harvest that he has reaped by his labours, which have now extended over a period of eight years. J. E.

THE LATE SIR SAMUEL BAKER.

NOTHING impresses more vividly upon one the rapid unfolding of our knowledge of Africa than the fact that the pioneers who forced the first paths into the unknown interior have survived to see generation after generation of younger men, who followed in their footsteps, fall victims to the fatal fascination of that continent. Burton, Grant, and Oswell, the companion of Livingstone's earliest journeys, have died so recently that we realise with a feeling of sorrowful surprise that the last of the first great group of explorers has passed away in the person of Sir Samuel White Baker, on December 30, 1893.

He was born in London in 1821, and after his school education turned his attention to engineering, but his professional work never took so thorough a hold upon his mind as the love for travel and sport, which his private means fortunately enabled him to gratify to his heart's content. Baker first went to Ceylon for elephant shooting in 1845, and saw a great deal of the island in subsequent years. Two books resulted from this experience—"The Rifle and Hound in Ceylon," published in 1854, and "Eight Years' Wanderings in Ceylon," in 1855. The study which he made of the climate of the elevated part of Ceylon led him to establish a colony of English agriculturists, fully equipped with a stock of cattle and sheep, at Nowera Eliya, over 6,000 feet above the sea, which is now a noted health resort. On the death of his wife, in 1855, he went to the Crimea, and carried out some railway work subsequently on the Black Sea coast. In 1860 he married a Hungarian lady, who survives him, after being his devoted companion through the trying years of African adventures, and in the pleasanter wanderings of his later life.

In 1861 he went to Egypt, resolved to carry on an extensive scheme of exploration at his own expense. With this object he spent a year in Abyssinia, working out the complete hydrography of the Atbara and its tributaries, and then started from Khartum to follow up the White Nile itself. In February, 1863, he met Speke and Grant at Gondokoro, returning from their great journey to the

Victoria Nyanza, and a year later Baker was able to supplement their discovery by arriving on the shores of the Albert Nyanza, the size of which he considerably over-estimated. He did not return to London until 1866, and found his fame as a traveller established. He received many honours, including that of knighthood and the gold medals of the Royal Geographical Society and the Paris Geographical Society; but in the following year, again accompanied by Lady Baker, he returned to Africa. The story of his first journey is recorded in two fascinating books—"The Albert Nyanza Great Basin of the Nile," in 1866, and "The Nile Tributaries of Abyssinia," in 1867. In 1869 he commenced the occupation of the upper White Nile provinces for the Egyptian Government, at the head of a body of Egyptian troops, and for five years laboured at the heavy task of restraining the slave-dealing Arabs and keeping in order his apathetic and often disaffected Egyptian subordinates. He established steam navigation on the Nile to the equator, and in his "Ismailia," published in 1874, told the story of the extension of Egypt. This completed his career as a pioneer and explorer; but a traveller he remained to the very end of life, and until last year he spent almost every winter either in Egypt or in India. He took a keen interest in the geography of Africa, and at critical moments in the course of recent developments in that continent he did not fail to give the benefit of his advice for the guidance of the country.

In 1879 he visited every part of the island of Cyprus, recording his impressions in "Cyprus as I saw it in 1879." The many reminiscences of his hunting adventures in every continent made his last book, "Wild Beasts and their Ways," a most valuable contribution to that liberal form of natural history which studies the lower animals as mankind is studied by the sociologist or historian rather than by the anatomist or physiologist. Baker was elected a Fellow of the Royal Society in 1869, and received the official recognition of several governments and innumerable learned societies in all countries for his services to geography and to humanity. His health kept up to within a month of his death, and to the last he remained a keen sportsman. He died in his residence at Sandford Orleigh, Newton Abbot, in Devonshire, and his funeral takes place at Woking to-day.

NOTES.

The list of New Year honours contains the names of two men of science in the public service—Mr. Norman Lockyer, F.R.S., Professor of Astronomy in the Royal College of Science, and Mr. W. H. Preece, F.R.S., Engineer-in-chief to the General Post Office—upon both of whom have been conferred Companionships of the Bath.

We note with much regret that Prof. Milnes Marshall, F.R.S., of the Owens College, Manchester, met with a fatal accident while ascending Scawfell, on Sunday, December 31. A notice of his life and work will appear in our next issue.

We have to record the death of Mr. R. Bentley, Emeritus Professor of Botany in King's College, on December 24, at the age of seventy-two. Mr. Bentley became botanical lecturer at King's College in 1859, and three years later he was appointed professor of botany at the London Institute. He was twice—in 1866 and 1867—elected president of the Pharmaceutical Conference, and was well known for his works on pharmaceutical botany.

The death is announced of Mr. R. Spruce, the well-known botanist and explorer, in his 67th year. Rather more than forty years ago Mr. Spruce visited South America on behalf of the Royal Gardens at Kew, and successfully carried out some very important scientific investigations. He explored the river Amazon, and crossed the continent from the Atlantic to the Pacific. The introduction of the cultivation of cinchona into India was very largely the result of Mr. Spruce's work, and his fine collection of plants have done good service to commerce and to botanical science.

The chair of Agricultural Chemistry in the University of Tokio has been accepted by Prof. Loew, of Munich.

Mr. Smith Hill has been appointed Principal of the Aspatria Agriculture College, in succession to the late Dr. Webb.

We understand that the Queensland Government, in pursuance of their policy of retrenchment, have abolished the post of Government botanist hitherto held by Mr. F. M. Bailey.

Prof. W. H. Corfield has been appointed President, and Dr. P. F. Moline secretary, of the English committee of the International Congress of Hygiene and Demography to be held at Budapest this year.

Dalziel's correspondent at Copenhagen states that the time of Central Europe was adopted throughout Denmark on the first day of this year.

A prize of 1250 francs is offered by the Natural History Society of Dantzic for the best means of destroying the poisonous insects in the forests of Western Prussia.

We learn from the *Times* that the sum of £600 a year has been bequeathed to the trustees of the Mason College, Birmingham, by the late Mr. Aubrey Bowen, of Melbourne. In making the bequest the testator stipulates that the trustees shall apply the sum in founding six scholarships of £100 a year each in connection with the college, to be called respectively the first, second, and third Bowen scholarships, for the promotion of the study of metallurgy, and civil, mechanical, and electrical engineering; and the rest Priestley scholarships, for the promotion of the study of chemistry.

The refusal of the S.P.C.K. to withdraw a book by Prof. Percy Frankland because in it experiments on living animals were approved, has led Lord Coleridge to address a letter to the secretary of the Society, in which he says: "I have learned from what seems unquestionable authority that those who administer the affairs of the Society for Promoting Christian Knowledge have finally determined to range the society in the number of those favouring the practice of vivisection and advocating its horrors. It is my duty, as I regard it, to separate myself at once from such a body, and I have accordingly directed Messrs. Childs not to pay any further subscription to the society. As I informed you of what I should feel bound to do in the events which have happened, I shall not occasion the society any inconvenience."

The following officers of sections have been appointed for the meeting of the Australasian Association for the Advancement of Science, to be held at Brisbane this year:—Section A—Astronomy, Mathematics, and Physics: Vice-presidents, Mr. Clement Wragge and Mr. John Tebbutt; secretary, Mr. J. P. Thomson. Section B—Chemistry: Vice-president, Mr. J. B. Henderson; secretary, Mr. G. Watkins. Section C—Geology and Mineralogy: Vice-president, Mr. W. H. Rands; secretary, Mr. Hargreaves. Section D—Biology: Vice-presidents, Dr. A. Dendy, Mr. F. M. Bailey, and Mr. J. J. Fletcher; secretary, Mr. J. H. Simmonds. Section E—Geography: Vice-president, Mr. D. S. Thistlethwayte, C.E.; secretary, Major A. J. Boyd. Section F—Ethnology and Anthropology: Vice-presidents, Rev. James Chalmers and Mr. E. M. Curr; secretary, Mr. Archibald Meston. Section G—Economic Science and Agriculture: Vice-presidents, Mr. G. A. Coghlan and Mr.

James Tolson; secretary, Mr. Wm. Soutter. Section J—Mental Science and Education: Vice-presidents, his Grace Archbishop Dunne, Mr. G. J. Anderson, M.A., and Mr. D. Cameron.

An earthquake shock was felt in Shepton Mallet, Somerset, and neighbourhood on December 30, about 11.30 p.m., and another shortly after midnight. The direction of motion of the waves was apparently from north to south. Prof. F. J. Allen sends us the following description of what was noticed by some friends of his. "At about 11.20 p.m. a shock was felt by three persons in one house; and about an hour later a second and more severe shock was observed by two of these persons. In another house, a quarter of a mile distant, three distinct shocks were felt by several persons. Both these houses are situated on the south side of the valley, whereas the reports published in the papers refer more particularly to movements observed on the north side. For those who are not acquainted with the district, I would mention that the strata (Carboniferous limestone, with overlying Trias, Lias, and Oolite) are very much disturbed, and present many interesting studies of horizontal as well as vertical faulting. It is just the kind of spot in which one might expect to have superficial movements occurring from time to time."

A letter from Prof. S. J. Bailey, of the Harvard College Observatory, to the editor of *La Bolsa*, published at Arequipa, Peru, gives an account of the establishment of the meteorological station on the summit of the Misti, in the Peruvian Andes, at an altitude of 19,300 feet above sea level, this being at present the highest observatory in existence. The fatigues undergone by observers ascending the conical peak from Arequipa are such as to render exact observations impossible, and it was therefore found necessary to construct a mule-path to the summit from a stone hut erected at an elevation of about 16,000 feet. This hut was erected on the north-east slope, being the most accessible side of this peak, which maintains its aspect of an isolated symmetrical cone from all points of view. On September 27 the summit was reached by Prof. Bailey, his assistant, several Indians, and two mules. The latter could hardly be made to go more than twenty paces without a rest. On October 12 the summit was revisited with two members of the Arequipa observatory, twelve Indians, and thirteen mules carrying materials for erecting two huts, and the registering meteorological instruments, comprising a barograph, a thermograph, several mercury thermometers, an hygrometer and anemometers. Each of the registering instruments works for ten days, and a member of the observatory will visit the station three times a month. A store of provisions is kept at the stone hut, and of the wooden huts at the top, one, provided with double wooden walls, is intended for the observer, the other for the instruments.

With regard to meteorological work in Australia, Sir Charles Todd remarked at the last meeting of the Australasian Association for the Advancement of Science, that in New South Wales there were 175 meteorological stations and 1063 rain gauges; in Victoria, 31 meteorological stations and 515 rain gauges; in South Australia, 22 meteorological stations and 370 rain gauges. In Australia there were 385 meteorological stations and 2580 rain gauges. During the last four years the forecasts issued in South Australia have been justified to the extent of 73 per cent., partially justified 20 per cent., and wholly wrong 7 per cent.

The radius of curvature of the cornea, together with the indices of refraction of the various refractive media of the eye, constitute the experimental data for determining the most important points about the eye. Drs. H. C. Chapman and A. P. Brubaker have measured this radius in fifty individuals by means of the ophthalometer (Proc. Acad. Nat. Sci., Philadelphia, 1893, p. 349), and they have found that in the average young man it amounts in the horizontal meridian to 7·797 mm., and in the vertical meridian to 7·552.

The Director of the Central Meteorological Observatory of Mexico, Señor M. Bárcena, has published an interesting pamphlet on the climate of the city of Mexico, based on the hourly observations of sixteen years 1877–92. Mexico, from its position of 7431 feet above the sea, and latitude 19°, might be supposed to be subject to great extremes of temperature, but as one geographical element neutralises the other, the result is a temperate and agreeable climate. The mean annual temperature is 59°·7, and the monthly means vary from 53°·6 in December to 64°·6 in May. The absolute maxima in the shade vary from 73°·4 in December to 88°·9 in April, while the absolute minima vary from 28°·9 in December to 46°·8 in August and September. The greatest daily range amounted to 41° in the month of March. The mean annual rainfall amounted to 23·8 inches, the wettest months being June to September; the greatest fall in one day was 2·5 inches in August 1888. The prevalent wind is north-west, which blows during most part of the year, and is the coldest and wettest quarter. The strongest wind blows from the north-east; the greatest hourly velocity observed during the sixteen years was about 56 miles per hour.

A detailed investigation of the properties of mirror silver chemically precipitated on glass is published by Herr H. Lüdtke in *Wiedemann's Annalen*. The three modifications of silver obtained in the wet way, termed by H. Vogel the arborescent, the powdery, and the mirror variety respectively, have been recently enriched by Mr. Carey Lea through his discovery of colloid silve . Herr Lüdtke thinks that this last variety and mirror silver are closely allied; that the latter, when newly formed, is indeed identical with the former. The electrical resistance of several varieties of mirror silver decreases considerably with their age. No such decrease was, however, observed in the case of mirrors produced by Martin's process or by that of Liebig, *i.e.* reduction by means of milk-sugar. On introducing a pole of ordinary silver and one of allotropic mirror silver into a weak acid or salt solution, and closing the circuit, a current was obtained indicating a difference of potential of about 0·1 volt between the two varieties, the allotropic variety being the positive pole. These conditions were reversed if the solution was one of silver nitrate, but the difference of potential was less. Lehmann's surmise that the precipitation of the mirror on the glass is due to a thin layer of sodium silicate, was invalidated by precipitating it on mica, porcelain, quartz, and platinum by the same methods.

The *Philosophical Magazine* for the present month contains a paper, by H. Nagaoka, on the hysteresis attending the change in length produced by magnetisation in nickel and iron. The author at first used the interference fringes produced between a plano-convex lens and a plate of plane glass attached to the end of the rod under examination to measure change in length. He found, however, that it was impossible to keep the temperature of the apparatus constant during the time necessary to make an observation, and also that there was considerable difficulty in counting the number of fringes displaced. To overcome the temperature difficulty the author has made use of the principle of the gridiron-pendulum, and has by this means succeeded in almost entirely overcoming this difficulty. In place of the interference bands he uses an optical lever, that is, a mirror fixed to a small base, to which are attached three needle points, two of these rest in a grove on the base-plate of the instrument, while the third rests on a small glass plate fixed to the end of the iron or nickel rod. The rod was placed along the axis of a solenoid which lay in a horizontai position pointing

magnetic east and west. The deflection of the mirror was measured by means of a microscope with a micrometer eyepiece, such that one division of the scale corresponded to a deflection of the mirror of 0″·295 of arc, or to an elongation of $0·805 \times 10^{-7}$ c.m. Experiments were made on wires of iron and nickel of different lengths, and he finds in every case that the elongation in iron and the contraction in nickel by magnetisation is accompanied by marked hysteresis. The curve of hysteresis is symmetrical with respect to the line of zero magnetising force, so that the elongation or contraction during cyclic changes is an even function of the magnetising force. When a wire has been magnetised it cannot be brought to its original length by simply reversing the magnetic field.

IN a note communicated to the same number of the *Philosophical Magazine*, Prof. Knott calls attention to the similarity between the effects observed by Mr. Nagaoka, and those which he has himself observed in the case of magnetic-twist cycles for iron and nickel. A steady current was passed along the wire under observation, and the longitudinal field acting on the wire was gradually altered between the limits $\pm$H, and at suitable intervals observations of the twist made. It was found that with a small range of field the hysteresis curve obtained by plotting twist against field was very similar to the well-known hysteresis curve of magnetisation. With limiting fields, however, stronger than the field which produces the maximum twist, the hysteresis curve crossed itself twice and formed three loops. In the magneto-elongation cycle the change of sign of the magnetising force does not produce a change of sign in the elongation. On the other hand, in the magnetic-twist cycle, as the magnetic force passes through zero from positive to negative, the twist tends to do the same, though with a lag. The author considers that the twist, under a given combination of circular and longitudinal magnetising forces, depends not only upon the elongations but also upon some function of these forces which changes sign with each, and to which the existence of the maximum twist is largely if not entirely due.

AN entertaining chapter on minerals, and the popular superstitions connected with them in Germany, is contributed to *Die Natur* by Friedrich Klinkhardt. The fact that variety among minerals is less easily perceived than that among plants and animals, is emphasised by the great influence that "a stone" pure and simple, without further specification, is capable of exerting in the popular estimation. Children under the age of one may not play with stones, otherwise bread will be scarce. An ill omen may be made innocuous by throwing a stone into the road before taking the next breath. Chalk is credited with many virtues, and is used both for its own efficacy and for making signs with. Cows marked all down the spine with chalk consecrated at Epiphany, remain healthy, and always find their way home. Alabaster in water is used for curing sick children in Bohemia. A flint pebble from the brook, if thrown over the roof into the poultry yard, encourages the hens to lay eggs. The beliefs connected with "thunderbolts," which are sometimes flint instruments, or quartz crystals, or lightning tubes, are exceedingly numerous. In the Palatinate it is believed that thunderbolts, after penetrating seven yards into the ground, rise a yard every year; this reminds one of Miölnir, Thor's hammer, which returned to his hand.

WE read an interesting paper "On the Kulm District of Lenzkirch in the Black Forest," by Dr. Rafael Herrmann. A geological map of the district is given, scale 1 : 50,000 (*Berichte der Naturforschenden Gesellschaft zu Freiburg i. B.*, June, 1893). In the Black Forest, just as in the Hartz and in Thüringia, two main series of carboniferous rocks are recognisable, an older group of dark shales, and a younger formation of conglomeratic rock. During the intermediate epoch, the upraising and folding of the rocks took place, associated with intrusions of crystalline rock. The eruptive rocks of the district are granite, coarse and fine grained, granitite, granitic dykes, quartz porpyhry, porphyritic dykes, and porphyritic breccias. Herrmann does not agree witk Vogelgesang that the granite and granitite are petrographical varieties of one and the same rock united by a complete transitional series, but regards them as two independent masses of rock, differing in composition and structure. All the granitic rocks have been intensely affected by pressure, whereas the younger porphyry shows no appearance of it. Herrmann deduces, therefore, that the intrusion of porphyry marks what was probably the last phase of folding and overthrusting of rocks in the Black Forest during the Carboniferous period.

THE region watered by the upper part of the Yenisei (which is known to the Mongols under the name of Ulu-Khem, and is made up by the confluence of the Bei-khem and the Kha-khem) belonged until lately to the least known parts of north-west Mongolia. The opinion expressed in the "General Sketch of the Orography of East Siberia" (*Zapiski* of the Russian Geographical Society, vol. v. 1874), to the effect that it must be a high plateau, and that the so-called circular chain Erghik-targak-taiga is nothing but a border ridge, or often but the steep slope of the plateau, had been contested. Now it finds its full confirmation in the recent exploration of the region by Mr. Kryloff, published, with a map, in the *Izvestia* of the Russian Geographical Society (vol. xxix. 4, 1893). The whole region really has the above-menioned character. After having left the valley of the main river, which has, even at the junction of the two Khems, an altitude of 1873 feet, Mr. Kryloff had to travel all the time on the level of the high plateau, never finding altitudes less than 3000 feet, till he returned to the Russian dominions in the basin of the Tuba. Mr. Kryloff's journey having been performed for the St. Petersburg Botanical Garden, special attention has been paid by the explorer to the flora of the region; and he found that the vegetation on the plateau assumes in many places the character of a Steppe vegetation, namely, in the flat but high valleys of the rivers, which are dotted by numerous small lakes. At the sources of the Bei-khem, the flat surface of the water parting, as well as large portions of the plateau itself, raise above the level of the tree-vegetation, usually marked by the cedar, and are covered with Alpine meadows. As to the ridges which rise above the surface of the plateau, they attain heights of over 7000 feet, and over 8000 feet in the Tannu-ola ridge in the north of Lake Ubsa-nor.

THE same number of the *Izvestia* contains a paper by M. M. Pomortseff, on his extremely valuable observations on the directions and angular speed of motion of clouds. The method resorted to for these observations is described at length, and the instrument which was used for this purpose is figured on a plate. The chief results are given on 94 separate small maps. The author himself sums up his results as follows:—(1) The middle of the cumulus clouds moves almost in the direction of the isobar which passes through the place of the observer. (2) The cirrus, cirro-cumulus, and cirro-stratus clouds move on a pretty long distance as a broad and nearly straight-line current—the direction of the stream being almost parallel to the part of the 760 mm. isobar which stands on the line connecting together the centres of two nearest and contiguous regions of high and low pressure. (3) There is doubtless a connection between the distribution of atmospheric pressure and the march of the barometer on the earth, and the vertical circulation of the atmosphere; but this connection does not extend farther than the height of the upper, *i.e.* cirrus clouds.

IN a letter addressed to the Russian Geographical Society from Lan-chou, in March last (*Izvestia*, vol. xxix. 4), Mr.

Obrucheff wrote that while crossing the plateau of Shan-si, he was enabled to supplement to some extent the observations of Richthofen; namely, he has discovered some fossil plants in the middle parts of the series of deposits which cover in China the carboniferous formation, and which Richthofen had described under the names of *Ueberkohlen-sandsteine* or *Plateau-sandsteine.* The plants unearthed by Mr. Obrucheff would indicate that the middle portions of this formation belong to the Mesozoic age, and are Triassic or Liassic. This formation spreads from Shan-si into the Shensi, the Alashan, and Gan-su, without losing in thickness, and probably represents an uninterrupted series of deposits from both the Mesozoic and the first half of the Cainozoic times.

We notice in the *Memoirs* (*Trudy*) of the Kazan Society of Naturalists (vol. xxvi. No. 2) a very interesting work by N. Wnukow, on the bacilli of leprosy. In addition to his own experimental researches, the author has carefully studied the West European and Russian literature of the subject, and has divided his memoir into three parts: the localisation of leprosy bacilli in the tissues of the human body; the inoculation of the bacilli to animals; and the artificial culture of the bacilli. The paper is accompanied by a coloured plate. The author's conclusions are:—The *Bacillus lepræ* is motile, and is found both within and outside the cells; but it has never been discovered in the cells of the epithelial layers of the skin or the mucous membranes. In the wounds the bacilli are brought to the surface, and undoubtedly may be transported on the skin of other individuals, thus becoming a cause of infection. Neither the injection of the pus containing leprosy bacilli, nor the grafting of pieces of skin taken from leprous patients to rabbits, could provoke leprosy in these animals. The bacilli introduced from man into rabbits and fishes, diminish in numbers after a time, and ultimately disappear. Most inoculated rabbits contract tuberculosis, but the illness must be ascribed in such cases to other causes than infection proper. As to the artificial culture of the *Bacillus lepræ*, it has failed with all culture media experimented upon by the author; the culture of *B. Uffreduzzi*, described by Eisenberg as leprosic, cannot be recognised as such.

An elaborate paper, entitled "Les Vibrions des Eaux et l'Etiologie du Choléra," by Dr. Sanarelli, has recently appeared in the *Annales de l'Institut Pasteur*, vol. vii. Numerous bacteriological examinations were made of the river Seine water above and below Paris, as well as of drain water, and the effluent of sewage after irrigation. In all no less than thirty-two vibrios were isolated, morphologically distinct, four of which gave the indol reaction, and in their pathogenic action on guinea-pigs could not be distinguished from the cholera-bacillus. Dr. Sanarelli is of opinion that there exist many varieties of vibrios, morphologically distinguishable, but capable of exciting in man and animals a disease in its morbid and clinical aspects identical with those regarded as typical of cholera, and that the conception of a restricted monomorphism is no longer tenable in the diagnosis of the cholera-vibrio. In all the more or less contaminated waters which were examined vibrios were present, finding in these surroundings conditions highly favourable to their existence and multiplication. It is possible that although the larger number of such vibrios may exist in the saprophytic or harmless state, yet probably pathogenic vibrios are more frequently present in such waters than has hitherto been suspected. Dr. Sanarelli points out that the saprophytic condition of some at least of these vibrios is, in all probability, due to the modification in and attenuation of their biological functions which residence in such media has produced. Thus an extremely virulent vibrio was reduced to a harmless saprophyte deprived of its pathogenic properties and power of producing the indol reaction, by being kept in boiled Seine water for a month, whilst even after three months it had undergone no change in its morphological condition. In the same manner that pathogenic organisms may be deprived of their virulence, it is conceivable that circumstances may arise under which they may recover their toxic character; so far, however, bacteriology has been unable to establish the correctness of this hypothesis, either in the laboratory or in actual experience.

For several years the State of Massachusetts has been attempting to exterminate the Gipsy Moth, and a Bill has recently been introduced into the House of Representatives to appropriate 100,000 dollars to rid the State of that troublesome insect. The *American Naturalist* points out, however, that the desired end can never be attained by merely hunting the moths in trees, hedgerows, and garden patches. In its future work, the Gipsy Moth Commission of Massachusetts should employ at its head a trained entomologist who should devote his time to finding and introducing some natural enemy to the pest. Moths, eggs, larvæ, and cocoons will escape the most careful of field agents, whereas insect parasites will keep the pest in continual check.

Messrs. T. D. A. Cockerell and Walter E. Collinge have published "A Check-list of the Slugs." It is a reprint from the *Conchologist*, vol. ii., 1893. The authority for the list is the first-named author; Mr. Collinge adds an appendix and notes; 628 species are recorded with very numerous varieties. There would appear to be a very ardent discussion as to the respective value of morphological and anatomical characters for the due determination of the species and varieties among these molluscs; but surely here, as elsewhere, the rational method would be to employ all such points of difference, whether external or internal, as may be found constant.

The Association for the Promotion of Home and Foreign Travel has issued a programme of tours arranged for this winter.

The December number of *Insect Life* is almost entirely taken up with the proceedings of the meeting of the Association of Economic Entomologists, held at Madison in August last.

Mr. C. Meldrum, the Director of the Royal Alfred Observatory, Mauritius, has issued his report for the year 1891, and also the results ot meteorological observations made at the Observatory during 1892.

A paper on "Technical Education in Glasgow and the West of Scotland: a Retrospect and a Prospect" read before the Philosophical Society of Glasgow in November last, by Dr. Henry Dyer, has been issued in pamphlet form. It is of interest to all concerned with matters of technical instruction.

Mr. W. Warde Fowler, a disciple of Gilbert White, has put on record his observations of the Marsh Warbler (*Acrocephalus palustris*) in Oxfordshire and Switzerland, and the differences between it and the Reed Warbler. His paper (issued by Simpkin, Marshall, & Co.) will be read with pleasure by all lovers of nature.

The number just issued of the Journal of the Royal Agricultural Society (vol. iv. part 4) contains several important articles. Mr. Carruthers describes the "Cross-fertilisation of Cereals," and his paper is given additional interest by means of seven good illustrations. "Water in Relation to Health and Disease" is treated by Prof. J. Wortley Axe, and under the title "Peat and its Products," Dr. Fream gives an account of the occurrence and utilisation of peat in various peat-producing countries of Europe.

Messrs. Baillière and Son have recently added to their series of works on chemical industries a volume entitled "Le

Cuivre," by M. Paul Weiss, in which the origin, mode of occurrence, properties, metallurgy, applications, and alloys of copper are fully treated. The author has visited the chief copper mines and works in Europe, and his book is a very useful *résumé* of the fundamental principles of the copper industry. The ninety-six figures inserted in the text include twelve excellent sections illustrating the molecular structure of various metals and alloys.

THE structure of snow-crystals photographed by G. Nordenskiöld formed the subject of an article in our last volume. Another important contribution to the subject has recently been published, namely, Prof. G. Hellmann's "Schneekrystalle" (Rudolf Mückenberger, Berlin). The work begins with a brief history of the study of snow-crystals, illustrated by reproductions of the various forms observed and drawn by different observers, from the spikes, crescents, and daggers of Magnus in the sixteenth century, to the elaborate and perfectly symmetrical stars designed by Glaisher. But in meteorology as in astronomy, photography is rapidly taking the place of the observer; so much, indeed, is this the case that the modern meteorologist and physical astronomer views visual observations with more or less suspicion. At any rate, the remarkably fine series of microphotographs of snow-crystals obtained by Dr. Neuhauss during the winter 1892-3, and reproduced in Prof. Hellmann's work, indicates that eye-observations of their forms are no longer necessary. After discussing the structure of snow-crystals, Prof. Hellmann proposes a classification into tabular and columnar crystals, the former class being subdivided into radiating stars, plates, and a combination of the two, and the latter into prisms and pyramids. A descriptive bibliography is given, thus increasing the value of a work upon a subject of which much more can yet be said.

THE cause of the violent explosion which usually occurs when any considerable quantity of metallic sodium is brought in contact with water in a more or less confined space, forms the subject of a communication to the *Journal für praktische Chemie*, by Prof. Rosenfeld. It has been hitherto supposed to be due to the formation of a quantity of sodium peroxide, by the decomposition of which oxygen is liberated, which mixes with the hydrogen produced in the main reaction, thus forming an explosive mixture. Prof. Rosenfeld has fully investigated the question experimentally. It was first established that steam may with impunity be passed over sodium contained in a slightly bent iron tube, no explosion ever occurring under these conditions. This would be quite compatible with the above explanation of the cause of the explosions, for any explosive mixture would be rapidly carried from the seat of the reaction by the escaping hydrogen or the excess of water vapour. No oxygen, however, was ever detected in the gas thus liberated. In all the experiments in which explosion was brought about by the action of water, whether in open vessels or in vessels closed by a water column, it was invariably observed that the sodium was blown to powder from the centre outwards—that is to say, the seat of the explosion was the interior of the piece of metal experimented with. Prof. Rosenfeld comes to the conclusion, from the whole of the phenomena observed, that the explosion is brought about by the sudden dissociation of a hydride of sodium which is formed in the first stage of the reaction. As such a compound can only be produced in an atmosphere of hydrogen, the only safe mode of decomposing water by metallic sodium is considered to be that previously mentioned, of passing a rapid current of steam over the metal; for the hydrogen is then removed from the sodium as quickly as it is produced, and the formation of hydride, and therefore all risk of explosion, is consequently avoided. In order to carry out this reaction an iron crucible is best employed which is capable of being closed in a gas-tight manner by means of an iron plate, which can be pressed firmly down against a flange on the edge of the crucible by means of a screw threading through a suitably supported nut. Steam is blown into the body of the crucible containing the sodium by means of a side tube, and the escaping hydrogen is led away by a similar tubulus upon the other side. If the supply of steam is arrested the moment hydrogen ceases to escape, solid caustic soda is obtained, mixed in a curious manner with more or less finely divided iron, probably owing to the formation of a quantity of an alloy of iron and sodium, which is subsequently decomposed with liberation of iron. Silver is likewise attacked in a similar manner. The method may also be employed to prepare solutions of soda of known strength. Thus, if twenty-three grams of sodium are employed, and the escaping hydrogen is washed through a little water, an exactly normal solution of soda can at once be obtained by dissolving the product in water, adding the wash water, and making up to a litre.

AN interesting investigation of the amount and nature of the gases occluded in the coal derived from several collieries in the Durham coal field has been carried out by Mr. W. McConnell, of the Durham College of Science. The collieries from which samples were taken are situate at different points along the same seam, known in Durham as the Hutton seam. It is bituminous coal used as gas-coal and as steam-coal. The coal or coal-dust was placed in an apparatus constructed entirely of glass, and which was capable of continuous exhaustion while heated in baths to known temperatures varying from 100° to 180°; the gas previously occluded by the coal was delivered by the pump into a receiving gas-holder, and subsequently measured and analysed. The coals from the Ryhope colliery were found to contain as combustible gases considerable quantities of occluded free hydrogen, marsh gas, ethane, and other members of the paraffin series of hydrocarbons as far as pentane. Moreover, a portion of the gas, consisting chiefly of the higher members of the paraffins and smaller quantities of olefines, is so firmly retained that crushing to fine powder and heating to 180° under reduced pressure is insufficient to remove it. It is also singular that the coal retains a remarkably high proportion of free oxygen in the occluded form, even after heating to 180°. In the case of the Hebburn colliery, a notably "gassy" mine, in which frequent "blowers" are met with, the results are especially interesting. The "blowers" deliver such large quantities of gas that some of it is actually "piped" up to the bank and burnt under the boilers. The combustible constituent of the gas thus utilised is found to be entirely marsh gas. The coal itself is found to contain a relatively very large volume of occluded gas, the combustible constituents being mainly marsh gas and ethane; and the ground coal and coal-dust yield in addition considerable quantities of higher members of the paraffin series. From the whole of the results derived from the various collieries, there can be no doubt that the coal-dust largely owes its sensitiveness to ignition to the denser occluded gaseous hydrocarbons which it retains so tenaciously.

THE additions to the Zoological Society's Gardens during the past week include a Leopard (*Felis pardus*, ♂, black variety), from India, presented by the Duke of Newcastle; a Herring Gull (*Larus argentatus*) from Jersey, presented by Mr. John Stanton; an Alligator (*Alligator mississippiensis*) from the Mississippi, presented by Mr. C. Knox Shaw; a Diamond Snake (*Morelia spilotes*) from Australia, presented by Commander A. Burgess, R.N.R.; a Diamond Snake (*Morelia spilotes*) from Australia, purchased.

OUR ASTRONOMICAL COLUMN.

PRIZES AT THE PARIS ACADEMY.—Among the numerous prizes presented by the Paris Academy (*Comptes Rendus*, No. 25, Dec. 18), those devoted to the science of astronomy were as follows:—M. Schulhof, the Lalande Prize, for his magnificent researches on comets; Dr. Berberich, the Valz Prize, for his well-known connection with the calculations of cometary and (minor) planetary orbits; and Prof. Langley, the Janssen Prize, for the work he has done relating to the distribution of the heat in the normal solar spectrum, and to the influence exerted on this distribution by both the solar and terrestrial atmospheres. Among the general prizes we notice that the Arago medal has been awarded to two American astronomers, Profs. Asaph Hall and Barnard. The former receives this medal as he was the discoverer of the two satellites of Mars, although on a former occasion he was the recipient of the Lalande prize for the same reason. The latter, it is needless to say, owes this honour to the fine use he made of the great 36-inch telescope of the Lick Observatory, in searching out the fifth, or, as it should be named, the first satellite of Jupiter.

THE TAIL OF COMET BROOKS (*c* 1893).—Last week, under this heading, we referred to Prof Barnard's remark that the fall of this comet had encountered some outside or obstructive medium. It is interesting, in the face of this, to look at the drawings of the great comet of 1882, and to notice the fragments and their relative positions and forms. With the drawing before us (Young's "Astronomy," 1888, p. 427) the following description is given:—"Besides this" (referring to that curious phenomenon called the *sheath*) "at different times, three or four irregular shreds of cometary matter were detected by Schmidt, of Athens, and other observers, accompanying the comet at a distance of three or four degrees when first seen, but gradually receding from it, and at the same time growing fainter. Possibly they may have been fragments of the tail which belonged to the comet before passing perihelion, or of the matter repelled from the comet when near perihelion. Since the comet, in passing the perihelion, changed the direction of its motion by nearly 180° in less than three hours, it was, of course, physically impossible that the tail it had before the perihelion passage could have made the circuit of the sun in that time. . . . Visible or invisible, the particles of the old train must have kept on their way under the combined action of the sun's gravitation and repulsion. . . ." Would not a more simple explanation in this case be that these fragments were the result of collisions near perihelion passage, for here most certainly we should expect to be in the presence of meteoritic matter in abundance, and these travelling at high speed?

THE PLANET VENUS.—This planet, which forms such a brilliant object in the evening sky, will during this month become brighter, reaching its maximum brilliancy on the 10th of January. For observers in northern latitudes its position is becoming more favourable for observation, owing to its movement northward in declination. A conjunction with the moon takes place on the 10th of January, so that about the day before and after that date these two bodies will form a striking pair.

GEOGRAPHICAL NOTES.

WITH the first of January the weekly South German geographical paper, *Das Ausland*, edited by Dr. Sigimund Günther, of Munich, and established as long ago as 1827, comes to an end, having sunk its identity by amalgamating with *Globus*, which for thirty-two years has been its North German contemporary and rival. *Globus* will continue to be published, with numerous illustrations, as heretofore, and with the additional attraction of Roman type being substituted for the old German character. It is somewhat remarkable that weekly papers of this kind, entirely devoted to geography and travel, with no political purpose, should be so thoroughly established in Germany and France, while no successful attempt has ever been made in an English-speaking country to start a similar publication.

THE Russian geologist, W. A. Obrucheff, who started in the early part of 1893 for a journey into the little known region of Ordos, lying in the great bend of the Hoang-ho, has (says *Globus*) been able to make many new observations. Leaving Tai-Yuen-fu, the farthest point reached by Richthofen in this direction, on January 18, and crossing the Hoang-ho on the ice on the 28th, he selected the route to Ning-hsia, across the south-western edge of Ordos, as the least known, with the intention of proceeding to study the mountains of Alashan and the left bank of the Hoang-ho, up to the Nan-shan range. On his way Obrucheff was able to throw some light on the hills between the plateau of Shan-si and Kansu, and the plain of Ordos, which he found to be only the denuded edge of the plateau, and in no sense a range. The portion of Ordos which he intended to cross is a blank on all maps, and the whole district in the great bend of the Hoang-ho north of the Great Wall is practically unknown territory.

THE last number of the *Verhandlungen* of the Berlin Geographical Society contains a short note on a journey to Hadramaut undertaken last year by a German explorer named Hirsch, whose experience gives some clue to the difficulties now being encountered by Mr. and Mrs. Bent. At the outset Herr Hirsch met with opposition from the British Resident at Aden, but overcoming this he reached Makalla and started for the interior, with two camels and a small party, on July 1. He ascended the Wadi Howere to the great plateau, and crossed the watershed at an elevation exceeding 6,000 feet. From the barren plateau Hirsch descended to the fruitful and populous Hadramaut valley, several of the towns of which were visited. At Terim he was very badly received, subjected to insults, and compelled to leave at very short notice, returning to Makalla through the scarcely known Wadis Bin Ali and Odym. Altogether the journey in the interior only lasted forty days, but observations of considerable value were made, which are now being prepared for publication.

A REMARKABLE discovery has been announced by the Austrian Institute for Historical Research, in the form of a copy of a map by Columbus, drawn on a letter written from Jamaica in July, 1503. This, although only a rough pen-and-ink sketch, shows exactly the opinion of Columbus himself as to the part of the world he had reached, which he believed to be the east coast of Asia. The original map, drawn by Columbus and his brother Bartholomew, was presented to Frate Hieronymo, who gave the map and a description to Alexander Strozzi, a noted collector of early voyages. He is supposed to have copied the original map on the margin of the letter of Columbus, which he had bound in a volume with other documents, and this volume is now in the National Library at Florence, where the existence of the map was discovered by Dr. R. v. Wieser, the Professor of Geography at Innsbruck.

NEW FRENCH LAW FOR THE PREVENTION OF FOREST FIRES.[1]

THE wooded tract of country comprising the hill ranges of Les Maures and l'Esterel in the departments of Le Var and Les Alpes maritimes, in the south-east of France, has been annually ravaged by forest fires from time immemorial. It is stocked with conifers, *Pinus Halepensis*, and *P. Pinaster*; the cork oak, and the pubescent variety of *Quercus sessiliflora*, and there is a dense undergrowth of *Erica arborea*, the roots of which are used for briar (*bruyère*) pipes, also of *Erica scoparia*, lavender, juniper, broom, dwarf palms, wild olive, and *Arbutus*, &c. During the months of June, July, August, and September, the drought, high temperature, and the violent *mistral* wind which prevail, increase the danger from forest fires and their severity.

Owing to the great destruction of property which these fires cause, a law was enacted in 1870, to be in force for twenty years, and has given excellent results, the frequency and extent of forest fires in the region having diminished by half during the period 1870–90. This law was renewed up to the present time, in order to allow Government to draw up a permanent law on the subject. The Minister of Agriculture accordingly drafted a bill, which, after consideration by a Committee of the Chamber of Deputies, and some unimportant amendments, was passed by the legislature, and received the consent of the President of the Republic, as a law, on August 19, 1893.

The principal clauses of the Act deal with methods of prevention and extinction of fires: thus the first clause prohibits, during the dangerous season above mentioned, all fires in forests

[1] The text of this Law is given in the *Revue des Eaux et Forêts*, vo xix. part 18, for September 25, 1893.

or shrubby waste lands, or within a distance of 200 metres from their boundaries. The period during which these fires were declared illegal by the former Act of 1870, was fixed annually by the prefects, but experience has shown that it can now be fixed once for all by the law. As exceptions to this law, Clause 2 also authorises the prefects to allow charcoal-makers and other woodmen to light fires at their own risk, in case of damage arising, and subject to certain rules made by the prefects.

Among the fires prohibited during the close season is the so-called *petit feu*,[1] by which strips of undergrowth were carefully burned every six or seven years in the cork forests, to save the valuable cork oak trees from more dangerous uncontrolled fires. This system costs only 3*s*. 6*d*. an acre, as compared with £4 an acre for uprooting the dangerous undergrowth. It is evidently more hurtful to the forest than the other method, as the fire occasionally gets out of control, and, in any case, the burning diminishes the fertility of the soil.

The ninth clause directs that all landed proprietors, whose land has not been entirely cleared of all woody growth, may be compelled by an adjoining proprietor to keep a strip of land between the two estates entirely free from shrubs or conifers. The breadth of this strip will vary, according to circumstances, between 20 and 50 metres.

It is further enacted in Clause 11 that similar bare strips 20 metres broad shall be kept up along all lines of railway through a wooded area, and that these strips in adjoining property shall be kept clear at the expense of the railway companies. As it may not always be necessary to keep up these fire lines along the railways, a committee, consisting of a departmental councillor (*conseiller général*), a forest officer, and a railway engineer, shall decide when they may be omitted. All proprietors, whose woods are cut down in clearing these strips, are to obtain indemnities. This is a new provision, and called for owing to the extension of railways. The Act looks to the future in a clause exempting railway companies from this liability if they should use electric motors, or other inventions which cannot cause a forest fire.

In case any fire should break out, and it may appear advisable to light a counter fire, the two fires meeting and extinguishing one another for want of inflammable material, the local mayor, or his deputy, or failing these the most senior forest officer present, is to take charge of all measures to extinguish the fire, and no indemnity arises for woods burned under such circumstances. As in India, it is found in the south-east of France that fire is frequently caused by sportsmen, or poachers during the dry season, and the prefect is therefore authorised to delay the commencement of the shooting season until the commencement of the rains, which generally happens before the end of September.

As it is found that the construction of a network of roads greatly facilitates fire protection, by giving more value to forest produce, and rendering it possible to transport the material cleared from fire lines, and as roads serve as lines from which counter fires may be started, the State offers a subvention of 3000 francs per kilometre (£200 per mile) for roads constructed in the district, up to a total outlay of 600,000 francs (£24,000).

It appears that since 1870, 479,000 francs (£19,160) have been spent by the State on new roads in the State forests of the Esterel. The penalties attached to the breach of the first clause of this law are one to five days' imprisonment, or fine of 20 to 500 francs, and both fine and imprisonment can be inflicted, so that magistrates can make the penalty proportional to the gravity of the offence, and all police, forest guards, whether belonging to the State or to private properties, are directed to carry out the law by reporting offences, their written statements being received as evidence in cases which may arise. If the railway companies do not clear the fire lines along the railways, these lines will be cleared at their expense by the French Forest Department.

Although much land which might otherwise be planted is wasted in England owing to heather fires, and not only is a large area of pine forest destroyed annually by fire, but also the increase of destructive pine beetles is thus greatly favoured, there is little hope of our Legislature interfering; but the matter is more serious in North America, and along the Northern Pacific Railway about 1000 miles of treeless country exists, where the forests have been destroyed by fires, whilst the immensely valuable pitch-pine forests of the Southern States are rapidly disappearing from the same cause.

Matters have been dealt with in British India much more prudently, and regulations against forest fires have been enacted for the last twenty years at least in all the provinces under our control, and also to a certain extent within the native States. As a result of these regulations, and the careful management of the Indian Forest Department, 23,144 square miles of State forest in India were protected from fire in 1891 at a cost of 9 rupees per square mile, and this in addition to large areas of evergreen forest where no danger from forest fires exists.

W. R. FISHER.

PRIZE SUBJECTS OF THE PARIS ACADEMY OF SCIENCES.

THE following are the subjects for which prizes will be awarded by the Paris Academy in the years 1894, 1895, 1896, and 1898:—

1894. *Grand Priz for Mathematical Sciences*—The developmen, of an important point in connection with the deformation of surfaces. *Priz Bordin*—The study of problems in analytical mechanics admitting of algebraic integrals with regard to veloc ties, and especially quadratic integrals. *Priz Francoeur*—Discoveries or useful works on the progress of pure and applied mathematical sciences. *Priz Poncelet*—To the author of the most useful work on the progress of pure and applied mathematical sciences. *Extraordinary Prize of six thousand francs*—For any work tending to increase the efficacy of French naval forces. *Priz Montyon*—Mechanics. *Priz Plumey*—To the author of an improvement of steam engines or any other invention which promotes the advance of steam navigation. *Priz Dalmont*—To the engineer of bridges and highways who presents the best work to the Academy. *Priz Lalande*—Astronomy. *Priz Damoiseau*—Improvement of the method of calculating the perturbations of minor planets so as to give their positions within a few minutes of arc for an interval of fifty years; also the construction of tables which allow the principal parts of the perturbations to be rapidly determined. *Priz Valz*—Astronomy. *Priz Janssen*—Astronomical physics. *Priz Montyon*—Statistics. *Priz Jecker*—Organic chemistry. *Priz Vaillant*—Study of the physical and chemical causes determining the existence of rotatory power in transparent bodies, especially from the experimental point of view. *Priz Desmazières*—To the author of the most useful work on all or part of the cryptogams. *Priz Montagne*—To the authors of important works having for their subject the anatomy, physiology, development, or description of the lower cryptogams. *Priz Thore*—Awarded alternately to works on the cellular cryptogams of Europe, and to researches on the habits or anatomy of a species of European insect. *Priz Savigny*—To young zoological explorers. *Priz da Gama Machado*—On the coloured parts of the integumentary system of animals, and on the fertilising matter of living things. *Priz Montyon*—Medicine and surgery. *Priz Breant*—For a means of curing Asiatic cholera. *Priz Godard*—The anatomy, physiology, and pathology of genito-urinary organs. *Priz Parkin*—Researches on the curative effects of carbon in its various forms, and more especially in the gaseous form of carbon dioxide, in cholera, different kinds of fever, and other ailments. *Priz Barbier*—For a useful discovery in surgery, medicine, pharmacy, or botany in connection with the art of healing. *Priz Lallemand*—For the recompensation or encouragement of works relating to the nervous system, accepting the widest meaning of these words. *Priz Bellion*—To the writers of works or discoverers of facts of special importance to the health of human beings or the improvement of mankind. *Priz Mège*—For the completion of Dr. Mège's essay on the causes that have retarded or favoured the progress of medicine. *Priz Montyon*—Experimental physiology. *Priz Pourat*—On the influence exercised by the pancreas and suprarenal capsules on the nervous system, and reciprocally, on the influence that the nervous system exercises on these glands, studied especially from a physiological point of view. *Priz Gay*—The study of subterranean waters; their origin, direction, the strata they traverse, their composition, and the animal and vegetable life that live in them. *Priz Montyon*—Unhealthy occupations. *Priz Cuvier*—For the most remarkable work on the animal kingdom, or on

geology. *Priz Trémont*—To the savant, artist, or mechanic requiring assistance to attain an object of use or benefit to France. *Priz Gegner*—For the assistance of the savant distinguished for his contributions to the positive sciences. *Priz Delalande-Guérineau*—To the young French explorer, or the man of science, who shall have rendered the greatest service to France or science. *Priz Jerome Ponti*—To the author of scientific work of which the continuation or development is important to science. *Priz Tchihatchen*—To the naturalist of any nationality who shall have pursued explorations in the Asiatic continent or neighbouring islands, having for their object the advancement of any branch of natural, physical, or mathematical science. *Priz Houllevigue*—Awarded in rotation by the Academy of Sciences, and by the Academy of Fine Arts. *Priz Cahours*—For the encouragement of young workers known for their interesting researches, and more especially for researches in chemistry. *Priz Alberto-Lévy*—For a means of preventing or curing diphtheria. *Priz Laplace*—To the head student of the Ecole Polytechnique.

1895. For the improvement of the theory of the relation between the flywheel and the regulator. *Priz Gay*—For a study of the régime of rain and snow over the whole surface of the earth. *Priz L. La Caze*—To the authors of the best work on physics, chemistry, and physiology. *Priz Delesse*—To the author of a work dealing with geology or mineralogy. *Priz Bordin*—For the memoir that adds most to the knowledge of natural history (zoology, botany, or geology) of Tonkin or one of the French possessions in Central Africa. *Grand Priz des Sciences Physiques*—For the work that contributes most to the advancement of French palæontology by dealing in a thorough manner with the vertebrata of the coal measures, and those of the secondary epoch, and comparing them with existing types. *Priz Chaussier*—For important works in legal or in practical medicine. *Priz Petit d'Ormoy*—Pure and applied mathematics or natural science. *Priz Leconte*—To be awarded (1) to the authors of new and important discoveries in mathematics, physics, chemistry, natural history, or medical sciences; (2) to the authors of new applications in these sciences. *Priz Gaston Planté*—To the French author of a discovery, invention, or important work in the domain of electricity.

1896. *Priz Janssen*—Astronomical physics. *Priz Serres*—On general embryology, applied as far as possible to physiology and medicine. *Priz Jean Renaud*—For the best work published during the preceding five years.

1898. *Priz Damoiseau*—For a development of the theory of the perturbations of Hyperion, the satellite of Saturn discovered simultaneously by Bond and Lassell in 1848, principally taking into account the action of Titan. Also to compare observation with theory, and thence deduce the mass of Titan.

SCIENCE IN THE MAGAZINES.

PROF. J. W. JUDD contributes to the *Fortnightly* an article on "The Chemical Action of Marine Organisms," dealing with the nature of the ocean-floor, and showing that the operations going on there are similar to those described by Darwin in his work on vegetable mould and earthworms. Prof. Judd favours the organic view of the origin of manganese nodules, and believes that the chemical theory is improbable. He says:—

"All the facts collected by the deep-sea exploring expeditions point to the conclusion that accumulation of material is going on with the most extreme slowness at these abysmal depths where the manganese nodules are found in greatest abundance, and it may well be that these slowly accumulating muds have been passed through the bodies of marine worms or other organisms an almost infinite number of times. At each passage of the clay through the organism a small addition of manganese and iron oxides would be made to the mass by the action of the living structure on the sea water, and thus in the course of time these oxides might be sufficiently concentrated to build up, by concretionary action, the remarkable nodules on the ocean-bed.

"Such action would be in complete analogy with processes going on both in fresh and salt water, by which calcareous, silicious, phosphatic, and ferruginous deposits are being everywhere formed in the waters of the ocean, while all theories of the direct separation of the manganese and rarer metals from their state of excessively dilute solution in sea-water by chemical reactions appear to me to be beset with the greatest difficulty. All the observations that have been made in recent years upon the deposits of the ocean-floor point to one conclusion, namely, that where materials have once passed into a state of solution in the waters of the sea they can only be separated from it in the open ocean by the wonderful action of living organisms."

Prof. Buechner discusses "The Origin of Mankind," his article being more or less a review of a pamphlet by Abel Hovelacque, entitled "Les débuts de l'humanité," in which the results derived from archæological researches are compared with the observations of travellers as to the lowest types of the human family that can exist. Captain Gambier, R.N., writes on "The True Discovery of America." He shows that Jean Cousin, a sea-captain of Dieppe, discovered the River Amazon in 1488, that is, four years before Columbus discovered San Salvador. There is clear evidence that Cousin was thoroughly conversant with all that was known of geography, hydrography, and nautical astronomy in his day, and that he sailed up the Maragnon, which was his name for the River Amazon as he heard it from the natives. On board Cousin's ship, as second in command, was a man named Vincent Pinçon, and Captain Gambier's contention is that this Pinçon was the same man as the Vincent Pinçon who is known to have commanded one of the ships under Columbus. The Pinçon that sailed with Cousin was tried by court-martial for insubordination when the ship returned to Dieppe, and was condemned to perpetual banishment from the soil of France. He went to Genoa, and from there to Palos, in Andalusia, where his two brothers carried on the business of shipowners and traders, making occasional voyages themselves. It is not too much to suppose that Columbus met the Pinçons, and was indebted to them for information about Cousin's voyage. Jealousy and human self-interest will explain why Cousin's name was carefully omitted from all writings referring to the discovery that was afterwards made by Columbus and the three Pinçons who accompanied him on the celebrated voyage.

In addition to these articles, the *Fortnightly* contains one in which Dr. Thin comments upon the most important points brought out in the Report of the Leprosy Commission in India.

The *New Review*, which appears for the first time this month as an illustrated review, contains an article on the late Prof. Tyndall, by Mr. P. Chalmers Mitchell. Sir William Flower contributes to *Good Words* an excellent description of the structure and action of "Birds' Wings." "The Vanishing Moose and their Extermination in the Adirondacks" is the title of a well-illustrated article by Mr. Madisson Grant in the *Century*. Mr. Grant says that the last moose in New York State was killed on the east inlet of Raquette Lake, in the autumn of 1861. In the *Century* also is related the circumstances that led to the first employment of chloroform, in 1847, by Sir James Simpson, the scribe being his daughter, Miss E. B. Simpson. Since chloroform may soon be superseded by some newer anæsthetic, it is well that the events which established it as the great alleviator of animal suffering have been recorded. Other magazines received by us are the *Humanitarian*, which reprints the address on "Biology and Ethics," recently delivered by Sir James Crichton Browne at Sheffield, *Scribner*, the *National Review*, *Contemporary*, the *Modern Review*, and *Longman's*, but none of these contain any articles of scientific interest.

THE RISE OF THE MAMMALIA IN NORTH AMERICA.

I.

IN a remarkable address delivered before the Zoological section of the American Association for the Advancement of Science, at the Madison meeting, in August, Prof. H. F. Osborn gave an account of the recent achievements of exploration and research in connection with the rise of the mammalia in North America, and suggested the lines along which further advances were desirable. The length of the address precludes its complete publication here, but the most important features will be found in the following extracts. Among the omitted portions are sections dealing with the origin and evolution of Trituberculism, the succession of the Perissodactyls, and that of the Artiodactyls, and the relation of the Ancyclopoda (Cope) to the law of correlation.

Twenty years ago an era opened in the mammalian palæontology of Europe and America. Partly inspired by the *Odontographie* of Rütimeyer, Kowalevsky completed and published in 1873 his four remarkable memoirs upon the hoofed mammals. He wrote these four hundred and fifty quarto pages in three languages not his own, in French upon *Anchitherium* and the ancestry of the horses, in English upon the *Hyopotamidæ*, in German upon *Gelocus*, *Anthracotherium* and *Entelodon*, including the first attempt at an arrangement of a great group of mammals upon the basis of the descent theory. These memoirs swept aside all the dry traditional fossil lore of Europe; they breathed the new spirit of Darwin, to whom the chief one was dedicated, making principles of descent of more importance than new genera and species. Kowalevsky thus summed up the contemporary palæontology:

"After the splendid osteological investigations of Cuvier had revealed to science a glimpse of a new mammalian world of wonderful richness, his successors have been bent rather upon multiplying the diversity of this extinct creation, than on diligently studying the organisation of the fossil forms that successively turned up through the zeal of amateurs and collectors. . . . With the exception of England (referring to Owen, Huxley, Falconer, and others), where the study of fossil mammalia was founded on a sound basis, and some glorious exceptions on the Continent (referring to Rütimeyer, Gaudry, Fraas, Milne-Edwards), we have very few good palæontological memoirs in which the osteology of extinct mammals has been treated with sufficient detail and discrimination; and things have come to such a pass, that we know far better the osteology of South American, Australian, and Asiatic genera of fossil mammals than of those found in Europe."

At the same time, between 1871 and 1873, the pioneers of American palæontology, Leidy, Marsh, and Cope, began the exploration of our ancient lake basins rich in life. The first ten years of their work not only revolutionised our ideas of mammalian descent, but brought together the data for the generalisations of the second decade; for Marsh's demonstration of the laws of brain evolution in relation to survival; for Cope's proof of ungulate derivation from types with the simple foot resting upon the sole, and with the ancestral conic or bunodont molar tooth; and finally for Cope's demonstration of the tritubercular molar as the central type in all the mammalia. These four generalisations furnished a new working basis for morphology and phylogeny.

In these twenty years, thanks to energetic field work, we have accumulated vast materials for the history of the rise of the mammalia, enough for ten students where there is one, and the questions arise: How shall we take best advantage of it? What methods shall we adopt? In this address, besides bringing before you the more recent achievements of exploration and research, I will try to illustrate the advances already made in lines of thought, observation and system in palæontology, and indicate other advances which seem to me still desirable. In the problem of how to think and work most effectively, and with most permanent results, all the sciences meet on common ground.

It is to the renown of the veteran Rütimeyer and of Kowalevsky, whose death we have to deplore, that, while their main inductions suffer by American discoveries, their methods of thought have not been displaced. It matters little that their theory that ungulate molars sprang from lophodont or crested forms, has been disproved; that Kowalevsky's tables of descent are full of errors; that his main generalisation as to the persistence of adaptive and extinction of inadaptive foot types does not hold good; that the horses and Anchitherium spring not from Palæotherium as he supposed, but from *Pachynolophus* and *Hyracotherium*, types which he carefully studied and yet omitted from the horse line! It is the right system of thought which is most essential to progress; better in the end wrong results such as the above, reached by the right method, than right results reached haphazard by a vicious method. If a student asked me how to study palæontology, I could do no better than direct him to the *Versuch einer natürlichen Classification der fossilen Hufthiere*, out of date in its facts, thoroughly modern in its approach to ancient nature. This work is a model union of the detailed study of form and function with theory and the working hypothesis. It regards the fossil not as a petrified skeleton, but as moving and feeding; every joint and facet has a meaning, each cusp a certain significance. Rising to the philosophy of the matter, it brings the mechanical perfection and adaptiveness of different types into relation with environment, the change of herbage, the introduction of grasses. In this connection it speculates upon the causes of the rise, spread and extinction of each animal group. In other words the fossil quadrupeds are treated *biologically*—so far as is possible in the obscurity of the past. From such models and from our own experience we learn to abandon such traditions in the use of the tools of science as mere methods of description and classification, and to regard priority only in the matter of nomenclature.

To illustrate some of these modern methods, let us first look at the evolution of the teeth in the rise of the mammalia. The teeth and the feet are the foci of mammalian evolution, the only direct points of contact with food and the earth. Their combined use in phylogeny has increased in interest, because their evolution has proved to be wholly independent. We recall Cuvier's famous claim, of which Balzac said at the time: "Rebuilt like Cadmus, cities from a tooth."

No generalisation has been more thoroughly routed than that of a necessary law of correlation between tooth and foot structure. Besides the orthodox clawed carnivores and hoofed pachyderms of the great French anatomist, we have discovered hoofed carnivores such as Mesonyx, and clawed pachyderms such as Chalicotherium. Even the apparently lasting barriers of correlation, which Owen raised between the even and odd-toed ungulates, have broken down by Ameghino's discovery of a Litoptern odd-toed horse with an even-toed type of astragalus. Not only is there no correlation of type, but none in the rate of evolution. Hipparion, the most progressive horse in tooth-structure, probably owed its extinction to its conservative preservation of its ancestral three toes. For these reasons the teeth and feet, owing to the frequent parallels of adaptation, may wholly mislead us if taken alone; while, if considered together, they give us a sure key; for no case of exact parallelism in both teeth and feet between two unrelated types has yet been found, or is likely to be. This, I believe, is the one lesson of later work which reverts to older methods; we should not base either classification or descent upon the teeth or feet alone. Every additional character diminishes the chances of error.

Lower Mesozoic Pro-mammalia.

With the exception of the triassic *Theriodesmus* of Seeley, no mammal is known by its limbs or skeleton until we reach the basal Eocene; in studying the first steps in the rise of the mammalia, we are thus practically driven to the teeth and jaws alone. In these straits of the fossil-hunter, embryology has lately come to our aid.

Assuming their remote reptilian origin, agreeing with Baur and Kükenthal that the theriomorph reptiles were parallel with rather than ancestral to the mammals, and therefore placing before both groups the hypothetical *Sauro-mammals* in or below the Permian, we come to the old question which Huxley discussed in his famous anniversary address: "Was there a succession between Monotremes, Marsupials, and Placentals, or a parallel development from a common pro-mammalian type?" Then we look to the newer questions: "When were the Edentates and Cetaceans given off?"

Modern tooth science springs first from the recent demonstration of Rütimeyer's hypothesis of 1869, that the teeth of all the mammals centre around a single reptile-derived type. With a single exception, which I believe can be disposed of, various stages of trituberculism or a three-cusped condition have become the standard for the teeth, as pentadactyly has long been for the feet, except that this is developed within the mammalian stem, while our five fingers are a reptilian legacy. Second, it springs from the recent thorough exploration of the youngest jaws for evidences as to the primitive form and succession of the teeth. This also supports the reptile theory of tooth descent by proving, what has been in considerable doubt, that the Pro-mammalia had a multiple succession of teeth like the reptiles, and that even some of the modern mammals retain dim traces of four series of teeth.

The brilliant discoveries of Kükenthal, Leche, and Röse begin to show how in various ways the mammals early modified the regular succession of all the teeth by suppression of parts of the multiple series. This is the first thing to consider. The next is how heterodontism arose, how the rows of conic teeth were specialised in different parts of the jaw for three or four functions. As a certain number of teeth took up each function, the question arises whether their number or dental formula was

ever the same in all the mammals, for we know it is very different now. After the teeth were thus divided, some functions became more important than others, and established a monopoly, causing first a marked difference in the relative development of the series, which we may express in a dental curve, resulting finally in a loss of certain teeth. In the meantime began the special evolution of the form of the back teeth, or molars. Was this alike in all mammals; was it tritubercular? It is surprising how many problems of early relationship are at stake in the discussion of these simple processes.

Primitive Diphyodontism.

What does *succession* really consist in? It now appears that Baume was right in denying that the first tooth is the mother of the second; for the teeth of the lower as well as the upper series spring from the common epithelial dental fold (Schmelz leiste) which dips down from the surface and extends the whole length of the jaw; at intervals it buds off the dental caps (Schmelzkeim) of the first series; after these are separated off, the dental fold sinks and buds off the dental caps of the second series, always below and inside the first; thus the fold is the mother and the caps are sisters, twins, or triplets, according to the number of the series. In all young mammals, including the traditional monophyodont Cetaceans and Edentates, and excepting only the still unexplored Monotreme embryos, traces of two series of teeth have been found. Both Leche and Röse have detected evidence that the dental fold sometimes buds off parts of a third series, thus explaining the occasional reversion of supernumerary teeth on the inner side of the second series, and Leche has seen traces of budding preceding the first series—thus giving us vestiges of four successions!

All our perplexities as to the relations of the milk and permanent teeth, and the ingenious but mistaken hypotheses of Baume, Flower, Wortman, and Cope have sprung from our want of evidence of the regular and complete diphyodontism of the stem mammals. The solution is in brief that the "milk teeth" and the "true molars" are descended from the first series, while the second series is represented by the "permanent incisors, canines, and pre molars" and rudiments of dental caps beneath the true molars. The mammals early began to diverge from this primitive diphyodontism in many ways; apparently adapting the first and second series, respectively, to their infant and mature feeding habits; losing parts or all of one series or the other, and in some cases pushing teeth of the second series in among the first; this intercalation has been a most confusing factor to us.

In the Marsupials (Kükenthal) almost the entire first series became permanent; thus from the Jurassic period to the present time only a solitary fourth premolar of the second series has pushed out its elder-sister tooth, and Röse has observed that an outer upper-incisor also pushes up from the second series; the remainder of the second series still persist as rudimental dental caps beneath the first, even beneath the first and second molars! There are wide variations among the Placentals; thus in the lowest existing forms, the Insectivora, Leche finds that in the Shrew (*Sorex*) the second series is suppressed entirely, while in the Hedgehog (*Erinaceus*) of the twelve permanent teeth in the anterior part of the jaws five belong to the first series and seven to the second. We thus meet with the paradox, that among the "primitive" Marsupials and Insectivores the regular reptilian succession was early interrupted, while in all the "higher" mammals the reptilian succession of two series was retained in the anterior part of the jaw. Beneath the posterior highly-specialised molar teeth of both Marsupials and Placentals, the second teeth were early suppressed, although in the Edentates, which also originally had specialised molars, there is a typical succession of seven teeth behind the canine. These discoveries prove that the whale teeth, like their paddles, have acquired a secondary adaptive resemblance to those of the Icthyosaurs. How did the single and simple teeth of the Edentates and Cetaceans develop? Clearly by retrogression. As Leche points out in the aquatic Carnivora, in which the first series are degenerating. The single-series condition (monophyodontism) advances step by step with retrogressive simplification of the tooth form (homodontism); thus in the true seals, the eared seals and the walruses, as the permanent teeth become simpler, the milk teeth become smaller. The Edentates, so widely separated genetically, parallel the seals in tending to suppress the first series of teeth and simplify the crowns of the second series at the same time. We might jump to the conclusion that this gives us an explanation of the homodont and apparently monophyodont condition of the toothed whales, especially as it has been supposed they sprang from aquatic carnivora, but in this Order matters were reversed, for the first series persisted and the second series were suppressed and persist as a rudimental row of tooth caps buried in the jaw.

Each dental series has an adaptive evolution of its own, in Erinaceus the first series has an ancient and the second a modern form; in Ericulus both series are alike; in the Bats the first series is homodont, the second is heterodont (Leche); in the Edentates the first series is ancient and heterodont, the second is modern and homodont (Thomas, Rheinhardt), so among the Cetacea and Ungulata.

What deep and ancient clefts the different laws of succession mark between the Marsupials and these three Placental groups!

Primitive Heterodontism and Formula.

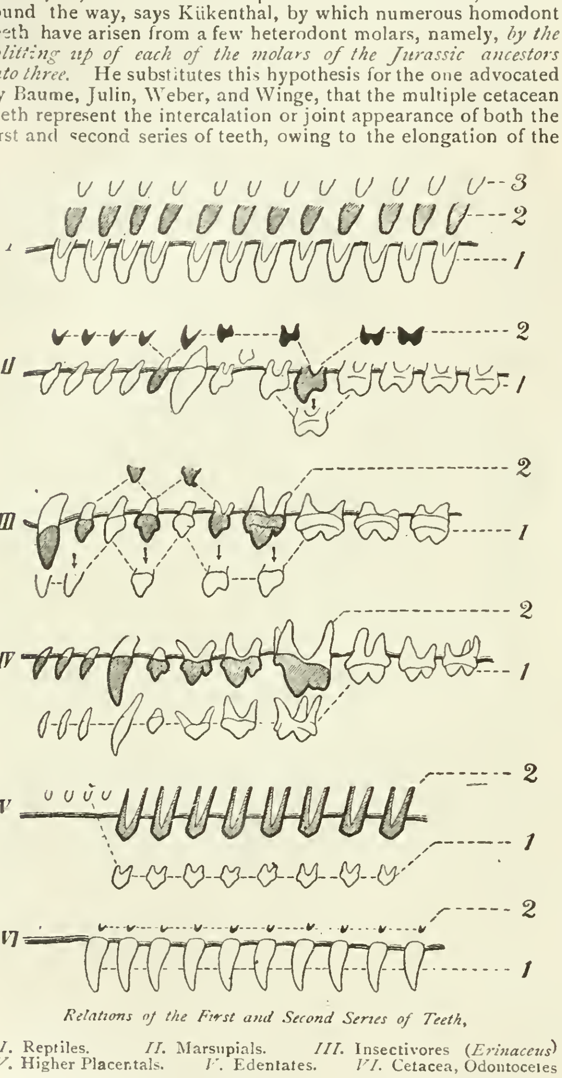
Now that all mammals are led back to a distant diphyodont stem, it is also true that the further we go back both in palingenesis and embryogenesis, the more widespread heterodontism is—all modern homodontism proving to be secondary. The simple conic teeth of the porpoise, for example, bear a misleading resemblance to those of a reptile. Flower, Weber, Julin, and Kükenthal agree that the ancestral whales and edentates were heterodont and had a smaller number of teeth than the existing forms.

Heterodontism is the second problem. Did the differentiation of the teeth into incisors, premolars, and molars occur before or after the Monotremes, Marsupials, and Placentals separated? It is well settled that the canine was the first maxillary tooth, and developed from the most anterior bi-fanged premolar; also, from the discovery of complete succession, we must now define the first molar as the most anterior specialised or triconid tooth, not as the most anterior permanent tooth. It seems to me we now find strong evidence that the stem mammals had a uniform number of each kind of teeth; in other words, a uniform dental formula. The Monotremes are most doubtful as the existing forms point only to primitive heterodontism. It will be a great step forward when we learn whether or not the Multituberculates are Monotremes—the resemblance of their molars to those of the duckbill is very superficial, for the duckbill upper molars lack the intermediate row of tubercles universally seen in the Multituberculates, and look to me rather like degenerate Trituberculate teeth. Cope has recently found in the cretaceous rocks a remarkable Trituberculate, which he names *Thlæodon*; the jaw of this animal is neither Placental nor Marsupial; it is like that of the Multituberculates—and both resemble remotely the degenerate modern Monotreme jaw. All we can say, therefore, is that the Multituberculates are an archaic group, highly specialised even in the Trias, that they were *probably* Monotremes, and neither structurally nor functionally akin to the Diprotodont Marsupials (Owen), nor to the Microbiotheridæ (Ameghino). With a dental mechanism and a condyle exactly like that of the rodents, they show no trace of canines, and the mode of evolution of their peculiar molars was probably paralleled later in the rodents. They present vestiges of a primitive dental formula like this: *I*3. *C*?. *P*4. *M*4+. *Thlæodon* shows *C*1. *P*4. *M*3. Thus, so far as this doubtful palæontological evidence goes, the Monotremes had a typical formula.

Our next step is to unify the typical 5. 1. 3. 4 of recent Marsupials with the 3. 1. 4. 3 of higher Placentals. Thomas has shown in his studies of recent Marsupials that they have probably lost one of the four typical premolars (*pm.* 2); this observation, fortunately, is partly confirmed by Röse's finding an embryonic germ of this tooth. Ignoring the incisors of the Jurassic Marsupials, Thomas raised the number of ancestral incisors to five, the highest number known among recent Marsupials; Röse therefore made another step towards uniformity when he showed that the Marsupial *i*.5 is probably a member of the second series of incisors, and should not be reckoned with the first. Now, if we suppose that the Placentals have lost one incisor, and one molar, abundant evidence of which is found in Otocyon, Centetes and Homo, we derive as the ancestral formula of both orders: *I*4. *C* & *P*5. *M*4.

The aberrant placental Cetacea point in the same direction, as we read in the conclusion of Weber's fine memoir: "All the

Cetacea sprang from a stem with a heterodont, but only partly specialised dentition (something like that of Zeuglodon, *I*3. *C*1. *P & M*). . . . not direct from Carnivores or Ungulates, but from a generalised mammalian type of the Mesozoic period, with some affinities with the Carnivora. . . . Zeuglodon itself branched off extremely early from the primitive line, and the heterodont Squalodon" (mark its formula, 3. 1. 4. 7.) "branched off later from the toothed whale line, after the teeth had begun to increase in number and before homodontism had set in." It would be easier for us while speculating to take Squalodon and the Odontocetes directly from the Jurassic mammalian formula (3. 1. 4. 8.). As for the multiplication of this formula, we have found the way, says Kükenthal, by which numerous homodont teeth have arisen from a few heterodont molars, namely, *by the splitting up of each of the molars of the Jurassic ancestors into three.* He substitutes this hypothesis for the one advocated by Baume, Julin, Weber, and Winge, that the multiple cetacean teeth represent the intercalation or joint appearance of both the first and second series of teeth, owing to the elongation of the



Relations of the First and Second Series of Teeth.

I. Reptiles. *II.* Marsupials. *III.* Insectivores (*Erinaceus*) *IV.* Higher Placentals. *V.* Edentates. *VI.* Cetacea, Odontocetes

jaw—a view which is now disproved by Kükenthal's discovery of the second row beneath the first. Since even by Kükenthal's hypothesis the typical Mesozoic mammals could not furnish as many teeth as are found in some of the dolphins, a likelier explanation than his seems to be that as the jaws were elongated the dental fold was carried back and the dental caps multiplied. The Edentates, like the Cetaceans, point back to diphyodontism, and somewhat less clearly to a typical dental formula. We are here indebted to Flower, Rheinhardt, Thomas, Kükenthal, and Röse. It is their rudimental and useless first series which gives the evidence of heterodontism, while the second series has become adaptively rootless and homodont. The especially aberrant feature is that a double succession exists in the typical "true molar" region. The adult nine-banded Armadillo presents only eight maxillary teeth, seven of which are preceded by two-rooted milk teeth (Tomes); in the embryro Leche finds fifteen dental caps, of which only thirteen are calcified; this number probably includes the four rudimentary incisors observed by Rheinhardt. In the aberrant Orycteropus (Aard-Vark), with ten adult teeth, Thomas finds seven milk teeth behind the maxillary suture (thus taking us into the molar region of the typical heterodonts). The last of these milk teeth is large, and two-rooted; behind this are three large permanent posterior teeth, apparently belonging to the first series. The large lateral tooth of Bradypus is suggestive of a canine. From this rapidly accumulating evidence it appears probable that the ancestral Edentates had four incisors, a canine and eight or more teeth behind it, the double succession extending well back, so that the first series did not become permanent at the fifth tooth behind the canine, as in the Marsupials and higher Placentals. If these are primitive conditions, as seems probable from comparison with fossil Edentates, they carry the divergence of the Edentates, like that of the Cetaceans, back into the Mesozoic period. Comparative anatomy and embryology thus point back to highly varied branches of a generalised placental heterodont stem in the Mesozoic, and a much earlier divergence than we formerly imagined. Now let us see to what the early Mesozoic mammals point.

There are three distinct and contemporary Jurassic types, the Multituberculates, the Triconodonts, and the Trituberculates. Are not these the representatives of the Prototheria, Metatheria, and Eutheria? In the archaic Multituberculates we have seen a monotreme type of jaw and vestiges of a typical ancestral formula. The Triconodonts are a newer group, perhaps derived from the Domotheriidæ (incipient Triconodonts) of the Trias, although these appear to be aberrant; the typical forms extend from Amphilestes to Triconodon, and exhibit the first stages of development of the inflected Marsupial jaw. The Trituberculates include the Amphitheriidæ and Amblotheriidæ with true tuberculo-sectorial lower molars, like those of modern Insectivores; they alone exhibit the typical angular placental jaw—no reason can be assigned for calling them Marsupials, excepting the traditional reverence for the Marsupial stem theory. Now, it is very significant that the average dentition of these old but highly diverse forms, namely, Multituberculates, 3. ? 4. 6., Triconodonts, 4. 1. 4. 7., Trituberculates, 4. 1. 4–5. 8., is also the dentition to which the existing mammals apparently revert.

The third problem is from what type of molar tooth did the mammalian molar diverge?

(*To be continued.*)

SCIENTIFIC SERIALS.

Symons's Monthly Meteorological Magazine, December 1893.—In an article entitled "March to October, 1893," Mr. Symons deals with the temperature of the last eleven years in the north-west of London, with instruments identical in themselves and in exposure, with especial reference to the exceptional summer of the year 1893. The first two tables give the average monthly maximum in the shade, and the average maximum in the sun for 1883–92, compared with the mean values for 1893. In both cases the means of 1893 exceeded the average in each month, the excess of the shade maximum ranging from 1°·2 in September to 9°·7 in April, while the sun maximum shows an average excess of 7°·1, ranging from 1°·8 in July to 10°·8 in May. The tables showing the extreme maxima in shade and sun for each month of 1893, with the average of the highest reading in the ten corresponding months, again have plus signs in every instance in 1893, the greatest excess of the former being 10°·5 in April, while the mean of the eight months (March to October) shows an excess of 6°. The severe test of comparing the highest reading for each month of 1893 with the absolute highest reading in the corresponding month during the preceding ten years, shows that the season as a whole was unprecedented. The shade maxima were unequalled in April, June, July and August, the excess in April amounting to 5°·4, whereas in no other year of the ten have unequalled shade maxima occurred in more than two months. In some particulars August 1893 is unparalleled in thirty-six years. The shade temperature at 9h. a.m. on the 18th, viz. 84°·3, was 3°·5 higher than any other 9h. a.m. reading, and the shade maximum on the 16th to 19th all exceeded 90°, the only instance of this temperature being reached on three consecutive days.

Wiedemann's Annalen der Physik und Chemie, No. 12.—On the change of intensity of light polarised parallel to the plane of incidence by reflection on glass, by Paul Glan. The light reflected from a glass prism was compared with that of a petroleum flame by means of a polarising arrangement consisting of a doubly-refracting prism and a Nicoll, between which a Hofmann prism was placed in order to obtain a spectrum of the reflected light. For crown glass, the ratio of the intensity of the reflected to that of the incident light polarised in the plane of incidence ranged from 0·055 at 30° to 0·293 at 70°, the corresponding values for flint glass being 0·070 and 0·327.—Hydrodynamico acoustical investigations, by W. König. The turning moment exerted by a moving column of a fluid upon a disc suspended in it was subjected to experimental investigation, the torsion being balanced by a magnet. For very small velocities of the column of air employed the form of flow was uniform, but it was found impossible to keep it so in the case of any considerable velocities. The contemplated determination of all the dynamical conditions of Rayleigh's disc swinging in an organ pipe, and its application to the absolute measurement of sound intensities has not yet succeeded.—Experimental investigations concerning elastic longitudinal and torsional fatigue in metals, by Louis Austin. The wires experimented upon were 23 m. long, and were suspended in the tower of the Strassburg Physical Institute. It was found that longitudinal and torsional fatigue phenomena are subject to similar laws. The fatigue effects in copper, silver, and brass were, for torsion, as 7 : 3 : 2, and for tension, as 4 : 3 : 2 approximately.—On the properties of various modifications of silver, by H. Lüdtke.—On thermopiles made of electrolytes and unpolarisable electrodes, by A. Gockel.—On the magnetism of iron cylinders, by O. Grotrian.—On the passage of electric waves through layers of electrolyte, by G. Udny Yule.—On some modifications of the Thomson quadrant electrometer, by F. Himstedt.—A calibrated electrodynamometer, by J. W. Giltay.—A new method of measuring self-potentials and induction coefficients of induction, by L. Grætz.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, December 7, 1893.—Dr. Armstrong, President, in the chair.—The following papers were read:—An apparatus for the extraction and estimation of the gases dissolved in water, by E. B. Truman.—The magnetic rotation of hydrogen chloride in different solvents, and also of sodium chloride and of chlorine, by W. H. Perkin. The author confirms his previous observations on this subject, and also shows that isoamylic oxide and hydrogen chloride do not appreciably interact. The magnetic rotation of hydrogen chloride in isoamylic oxide solution is 2·245, in alcoholic solution 3·324, and in aqueous solution 4·300. The magnetic rotations of sodium chloride and of chlorine were also determined.—Analysis of water from the Zem-Zem well in Mecca, by C. A. Mitchell. The author gives analyses of water obtained by the late Sir R. Burton from the holy well in Mecca.—The preparation and properties of bromolapachol, by S. C. Hooker. Bromolapachol is obtained by reducing dibromolapachone; when dissolved in sulphuric acid it yields bromo-β-lapachone. The latter is converted into bromo-α-lapachone by the action of hydrobromic acid, whilst the reverse change occurs on dissolving the α-isomeride in sulphuric acid.—Studies on citrazinic acid (Part ii.), by T. H. Easterfield and W. J. Sell.—The oxides of the elements and the periodic law, by R. M. Deeley. The author obtains a new periodic diagram by plotting the atomic weights of the elements against the numbers obtained on dividing the densities of the oxides by the atomic weights of the corresponding elements.—The freezing points of alloys in which the solvent is thallium, by C. T. Heycock and F. H. Neville. The mean depression of the freezing point by the addition of one atomic proportion of gold, silver, or platinum to one hundred atomic proportions of thallium is 6°·31; the addition of lead to thallium, however, raises the freezing point.

Geological Society, December 20, 1893.—W. H. Hudleston, F.R.S., President, in the chair.—The following communications were read:—On the stratigraphical, lithological, and palæontological features of the Gosau beds of the Gosau district, in the Austrian Salzkammergut, by Herbert Kynaston. The author, after referring to the previous literature of the subject, treated of the situation and physical aspects of the Gosau valley, the distribution of the Gosau beds, their stratigraphy, palæontology, and geological horizon, and the physical conditions under which they were deposited, and a comparison was instituted between the Gosau beds and the equivalent beds of other areas. He showed that Hippurites occur at two horizons in the Gosau beds—a hippurite-limestone immediately above the basement-conglomerate being characterised essentially by *Hippurites cornuvaccinum*, which is overlain by *Actæonella-* and *Nerinæa-*limestones and an estuarine series, and above these was a second hippurite-limestone characterised essentially by *Hippurites organisans*. It was pointed out that Toucas similarly distinguishes two hippurite zones in Southern France, the lower, characterised essentially by *H. cornuvaccinum*, being placed by him at the top of the Turonian system, whilst the second, with *H. organisans*, is referred to the summit of the Senonian; and the author gave reasons for regarding the Gosau zones as the equivalents of those of the South of France, in which case the Gosau beds will represent the uppermost Turonian and the whole of the Senonian, *i.e.* the zones of *Holaster planus*, *Micraster*, *Marsupites*, and *Belemnitella mucronata* in England, whilst the upper unfossiliferous beds may be the equivalents of the Danian beds. The strata are, on the whole, of shallow-water origin, and were deposited in shallow bays in the Upper Cretaceous sea of Southern and Central Europe, on the northern flanks of the Eastern Alps. Probably towards the close of Upper Cretaceous times the southern area of the Gosau district was cut off from the sea to form a lake-basin in which the upper unfossiliferous series was deposited. Mr. W. Whitaker, Sir John Evans, and Prof. J. F. Blake spoke on the subject of the paper, and the author briefly replied.—Artesian boring at New Lodge, near Windsor Forest, Berks, by Prof. Edward Hull, F.R.S. The boring described in this paper was carried down from a level of about 220 feet above Ordnance datum through the following beds:—London Clay and Lower London Tertiaries, 214 feet; Chalk, 725 feet; Upper Greensand, 31 feet; Gault, 264 feet; Lower Greensand, 7 feet. The chalk was hard, and contained very little water; but on reaching the Lower Greensand the water rose in the borehole to a height of 7 feet from the surface. The author discussed the probability of the Lower Greensand yielding a plentiful water supply in the Windsor district. In the discussion that followed, the President said it was satisfactory to learn that there was an area near West London in which the Lower Greensand was full of water. He thought that the section exhibited by the author explained why it was full in that particular locality, for the rainfall about the extensive area of Hindhead, which lay nearly due south, must be considerable. Mr. W. J. Lewis Abbott and Mr. W. Whitaker also spoke, and the author replied.—Boring on the Booysen Estate, Witwatersrand, by D. Telford Edwards. An account was given of a boring on the Booysen estate, situated about two miles from Johannesburg, and about 5000 feet south of the nearest point of outcrop of the "Main Reef" of the Witwatersrand. The "Bird-Reefs" crop out generally at a distance of 4000 feet south of the Main Reef. The borehole, 1020 feet deep, passed through sandstones (often micaceous), quartzites, and conglomerates, the last-named having a collective thickness of 91 feet 7 inches, the two thickest reefs being respectively 26 and 22 feet thick. The dip of the beds was 35°. Traces of gold were obtained. All the reefs were highly mineralised, principally with iron pyrites, and belonged to the "Bird-Reef" series which overlies the Main Reef.

PARIS.

Academy of Sciences, December 26.—M. de Lacaze-Duthiers in the chair.—On the motion of Jupiter's fifth satellite, by M. F. Tisserand. A calculation of the displacement of the "perijove" of the fifth satellite due to the polar depression of Jupiter shows that it would amount to 882° per annum, or one revolution in nearly five months. It is hoped that powerful instruments will enable observers to verify this.—On the propagation of electricity, by M. H. Poincaré. Starting from the "telegraphists' equation," the author shows that when an electrical disturbance proceeds along a wire, the head of the disturbance moves with a velocity such that, in front of this head, the disturbance is nil, as in the case of light and of plane sound waves, with the difference, however, that the electric disturbance leaves behind a residue of finite magnitude.—Numerical verifications relating to the focal properties of plane diffraction

gratings, by M. A. Cornu. The verification of the theory of focal anomalies in gratings already published, by testing actual gratings showing such anomalies, was based upon the following theorem: When the observed pencils make a constant angle with the incident beam remaining fixed, half the sum of the azimuths of the grating corresponding to spectra of symmetric orders is constant, and equal to the azimuth corresponding to the reflected beam.—Remarks on the spontaneous heating and ignition of hay, by M. Berthelot. Hay dried and stacked under normal circumstances loses moisture and oxidises slowly, without being sensibly heated. The initial heating, where it takes place, is due to the action of ferments, but not the higher stages of the process. When the ferments are no longer capable of further raising the temperature without endangering their own existence, it often happens that purely chemical action steps in, and leads up to the ignition of the haystack. The temperature of ignition for these materials is far below red heat.—On the composition of winter drainage waters from bare and from cultivated soils, by M. P. P. Dehérain.—Observations of the minor planets 371 and 372 (1893) made with the great equatorial of the Bordeaux Observatory, by MM. G. Rayet and L. Picart.—The analysis of commercial butters, by M. C. Viollette.—On the approximate development of the disturbing function in the case of inequalities of higher orders, by M. M. Hamy.—Investigation of that part of the coronal atmosphere of the sun which is projected upon the disc, by M. H. Deslandres.—Is there oxygen in the sun's atmosphere? by H. Duner.—New applications of the tables of increasing latitudes to navigation, by M. E. Guyon.—On the successive radii of curvature of certain curves, by H. R. Godefroy.—Calculation of electro-magnetic forces, according to Maxwell's theory, by M. Vaschy.—On the diurnal variation of the tension of aqueous vapour, by M. Alfred Angot. The observations made at the top of the Eiffel Tower since the end of 1889 have shown that at the height of 300 m. the change of vapour tension during winter does not exceed a few hundredths of a mm. During the eight months beginning with March, a single maximum was observed during the day at 9 a.m., and a minimum at 5 p.m., while in the adjacent Parc Saint-Maur, there were two maxima, at 9 a.m. and 8 p.m., and two minima, at 4 a.m. and 4 p.m. It appears that the variation of vapour tension, as observed in ordinary meteorological stations, is a local phenomenon, limited to the lower strata of the atmosphere.—On the diurnal variation of atmospheric electricity, observed near the summit of the Eiffel Tower, by M. A. B. Chauveau. The indications of an electrometer registering photographically the potential of the air, lead to conclusions similar to those of the preceding paper. The two sets of maxima and minima observed on the ground are replaced by one set only, consisting of a maximum at about 6.30 p.m. and a minimum at 4 a.m. The potential, which sometimes exceeded 10,000 volts, was reduced to a convenient amount by the interposition of condensers in cascade.—On the weight of a litre of normal air, and the density of gases, by M. A. Leduc.—Sketch of a system of atomic weights of precision, founded upon the diamond as standard substance, by M. G. Hinrichs.—General method for the volumetric e timation of silver under any form, by M. G. Denigès.—On the stability in air of a 0·001 solution of corrosive sublimate, by M. Tanret.—Remarks on the critical pressures in the homologous series of organic chemistry, by M. E. Mathias.—On caseine and the organic phosphorus of caseine, by M. A. Béchamp.—On a new source of rhodinol, by MM. P. Monnet and Ph. Barbier.—Presence of camphene in essence of aspic, by M. G. Bouchardat.—On the volatile carbides of the essence of valerian, by M. Oliverio.—Contribution to the study of the ptomaïnes, by M. Œchsner de Coninck.—Influence of certain causes upon receptivity; bacterian associations, by M. V. Gattier.—Toxicity of the blood of the viper (*Vipera aspis L*).—Modifications of the emissive power of the skin under the influence of the electric brush discharge, by M. Lecercle.—Influence of iron upon the vegetation of barley, by M. P. Petit.—Influence of bark-stripping upon the mechanical properties of wood, by M. E. Mer.—On the natural dessication of grains, by M. H. Coupin.—On the oolitic strata of the Paris Tertiary, by M. G. F. Dollfus.

BERLIN.

Physiological Society, December 8.—Prof. Munk, President, in the chair.—Prof. A. Kossel gave an account of his further researches on nucleic acid, carried on in conjunction with Dr. Neumann. The acid, as obtained from the thymus, differs from that obtained from other sources, in that during its decomposition it yields only adenin; it has hence been distinguished as adenylic acid. It occurs in two forms: one readily soluble, the other soluble with difficulty. When boiled with water, this acid yielded a paranucleïc acid, which contained no adenin. By boiling with dilute hydrochloric acid a fourth acid (thyminic) was obtained, from which crystalline thymin could be obtained. All the above well-characterised substances possess, when analysed, an extremely complex constitution; thus the molecule of adenylic acid contains 75 atoms of carbon, and that of paranucleïc acid 90 atoms. Dr. H. Kossel had studied the action of nucleic acid on bacteria, and found that cholera-germs and streptococci are readily killed by small quantities of the acid; whereas anthrax germs are much more resistent. He therefore considered that the bactericidal action of lymph-cells was attributable, in part at least, to this action of nucleic acid.—Dr. Rawitz spoke on spermatogenesis in Hydromedusæ. Unlike all other animals, the spermatozoa in this animal are developed in the outer layer of the bell, and are discharged direct into the surrounding fluid. The same speaker further described curious large branching villi in the jejunum of Macacus, not met with in the intestine of other species of monkey.

THE KEW INDEX OF PLANT-NAMES.

Index Kewensis plantarum phanerogamarum nomina et synonyma omnium generum et specierum a linnaeo usque ad annum mdccclxxxv complectens nomine recepto auctore patria unicuique plantae subjectis. Sumptibus Caroli Roberti Darwin, ductu et consilio Josephi D. Hooker, confecit B. D. Jackson. Fasciculi II. (Oxonii: E prelo Clarendoniano, MDCCCXCIII.)

THE appearance in rapid succession of the first two fasciculi forming the first volume of this splendid work, to be fittingly known to all time as the "Index Kewensis," is an event of supreme importance not only to the widely limited section of the scientific world which is professedly botanical, but also to the much wider circle of those who are interested in plants, whether this be from their more strictly technical side as the source of economic products, or from their more general and popular one, as objects of pleasure in cultivation and decoration. With the completion of the work in the second volume, which we are glad to know is not likely to be delayed beyond the current year, everyone will have within reach a book of reference in which may be found the correct name, the synonymy, the authority for the name, and the title of the work in which it is first published, along with an indication of the native country of any flowering plant described before the end of the year 1885.

It is to Charles Darwin we owe primarily this valuable work. In a short preface to the first fasciculus, Sir Joseph Hooker gives the following concise narrative of its origin:

"Shortly before his death Mr. Darwin informed me of his intention to devote a considerable sum in aid or furtherance of some work of utility to biological science; and to provide for its completion, should this not be accomplished during his lifetime. He further informed me that the difficulties he had experienced in accurately designating the many plants which he had studied, and ascertaining their native countries, had suggested to him the compilation of an index to the names and authorities of all known flowering plants and their countries, as a work of supreme importance to students of systematic and geographical botany, and to horticulturists, and as a fitting object of the fulfilment of his intentions.

"I have only to add that, at his request, I undertook to direct and supervise such a work; and that it is being carried out at the herbarium of the Royal Gardens, Kew, with the aid of the staff of that establishment."

Everyone who has had dealings with plants will have realised the difficulties referred to by Mr. Darwin, and will welcome the issue of the "Index Kewensis" to which his munificence has given birth, and will congratulate Sir Joseph Hooker and Mr. Daydon Jackson on the result of their fifteen years' labour as the instruments through which the practical wish of Mr. Darwin is in process of being carried out. In passing, it is not uninteresting, from the point of view of history, to note the association of the name of Darwin with this Index. The biological sciences, whilst owing an eternal debt of gratitude to Linnæus for the order which he brought out of their preceding chaos, and for the binomial nomenclature his genius so deftly constructed as an alphabet of system, have reason to regret the retarding influence on their progressive development of the dogma of constancy of species which his scholasticism tacked on to his nomenclature, and which the nomenclature served to perpetuate. From the trammels of this dogma the genius and work of Darwin gave to biology final emancipation, and now by his forethought and munificence this enumeration of genera and species is being provided, the foundation of which rests on the enduring portion of the work of the great Swedish naturalist.

It is impossible to emphasise too strongly the value of the book before us. The most recent work of similar kind is the "Nomenclator Botanicus" of Steudel. But this was completed in 1841, and since that date the activity of botanists and the exploration of the world's surface has added so enormously to the known plants, that for practical purposes Steudel's Nomenclator has been for long out of date. The "Index Kewensis" is not, however, cast on quite the same lines as Steudel's work, and possesses valuable features absent from it. The Nomenclator was confessedly a critical botanical book, expressing the views of the limitation and relationship of genera and species held by the author, and consequently new names on the authority of Steudel occur throughout. The "Index Kewensis" makes no such profession. It takes the literature as it existed at the end of the year 1885, and from it is compiled, in conformity with certain definite guiding principles of plant-naming, the correct nomenclature, based, so far as the limitation of genera and species is concerned, upon the work of the most competent and trustworthy writers. The "Genera Plantarum" of Bentham and Hooker gives the standard of limitation of genera, and for species the conclusions of monographers and recognised authorities in the different groups supply the basis for the synonymy. The Index is therefore essentially a literary work carried out under effective botanical supervision, and the circumstances surrounding its production are most favourable. No one more qualified for this detailed work than Mr. Daydon Jackson, by his extensive knowledge of botanical literature and critical judgment, could have been found; in Sir Joseph Hooker the work has the supervision of the most experienced systematic botanist of the day; and Kew, the natural birthplace of a British book dealing with all flowering plants, affords unrivalled facilities for the investigation involved in such a work.

We have said the "Index Kewensis" gives the correct name of all plants described before the end of the year 1885. This brings up the much-discussed question of what is the correct name of a plant? Under what rules is it to be fixed? In its bearing on this question the Index appears most opportunely, and it may be regarded as the manifesto of the working British systematic botanists upon the vexed subject of plant-nomenclature; and a thoroughly practical one it is. Briefly the guiding rules of the Index are these:—The starting point for genera is the first edition of the "Systema" of Linnæus, published in 1735; the starting point for species is the first edition of the "Species Plantarum" of Linnæus, published in 1753; the correct name is that given by the author who first placed the plant in its proper genus. There is a soundness in these principles which should

appeal to any unprejudiced mind. If nomenclature dates from Linnæus, who founded the system, naturally the first editions of his works dealing satisfactorily with genera and with species, are respective points of departure for the names of these, and in dealing with the species described by subsequent authors a similar course must be pursued. This code has been the tradition of the representative British botanists, and to it the former leaders of American botany also subscribed. It is the simple rule that priority determines the name. But, as with other rules framed by frail humanity for its guidance, this, if applied with rigorous inflexibility, would defeat the object it is designed to serve. To drop a name which has become generally accepted as the designation of a plant, and with which it is always associated, and take up for it some unknown name, simply because some one has discovered that this one preceded that by a few months in publication, or because it occurs a few lines earlier on the page of the same work, may mean logical adherence to the rule of priority, but is subversive of the purpose of nomenclature. Conformity with the code has therefore on the part of the botanists mentioned been governed by circumstances of practical expediency. They have kept in mind that nomenclature is only an aid to, not the aim of, the study of plants, and that a theoretically perfect nomenclature is inconsequent by the side of one which in practice admits of the ready recognition of the plants named; they have thought more of the identity of the plant and of its relationships than of the technical accuracy of the name under generally guiding principles, and have not therefore hesitated to cite older and obscure names as synonyms, and to ignore them if their use would replace others which had come to be generally and widely known. This principle of expediency and convenience, it has been said, is an unstable one, and to workers in fields of science in which it is not admitted may appear to be a mistake. But in the past of botany, in the hands of men really endeavouring to increase the general store of knowledge of plant-life, it has worked well. No doubt inconsistencies and mistakes may be found in the works of botanical writers who have acted upon it, traceable to a laxity which it introduces; but it has been a strong conservative element in nomenclature, whereas the application of the rule of strict priority has been most unsettling. For there are, unfortunately, men endowed with antiquarian zeal mated with sentiment which deems the naming of a species honour, and of a genus glory, who ferret through the pages of forgotten or unknown tracts or obscure journals, which perchance may contain a name, given by an author whose work has perhaps had no effect whatever upon the progress of the science, with which, under strict priority rules, they may supplant one custom has made part of popular language; or who rake out of correspondence (alas, that its preservation should serve such end) the history of private quarrels and jealousies of men whose names, as the roll of time has handed them down to us, carry only the attribute of scientific distinction, with the object of showing that one may have ignored the work of another, preceding it by a few days or weeks, and that consequently firmly established names must give place to those which strict priority demands. It is through such work, revelling in the overturning of authorities, which does not contribute to the progress of botany, and is essentially non-botanical, that many of the difficulties in nomenclature arise, and it merits the censure of all true botanists. Such work proves the wisdom of the botanists who have held aloof from binding agreement to strict priority rules, and against the load of synonymy and the confusion the strict priority rule would in these ways inflict upon plant-nomenclature, expediency and convenience are the protection to which appeal can be made. We are glad to note that in the "Index Kewensis" discretion has been exercised, and familiar and generally known names have not been sunk, although under the strict priority rule they should have been replaced by other and obscure ones.

That the procedure in the Index will meet with the universal acceptance of botanists may be hoped for; it cannot be expected immediately, when we have regard to the existing divergencies upon fundamental points. The laws of nomenclature formulated by the Paris Botanical Congress of 1867, made strict priority the basis of nomenclature, and were so generally adopted by systematic botanists out of England, that little was heard of the subject in subsequent years until a revolt of the younger American botanists against the practice of their former leaders—adherents to the line of expediency—brought it so prominently under notice a few years ago, that it has since been a staple of discussion in some botanical journals. Strict priority was the cry of the Americans, and some of them, with a zeal tinged with pedantry rather than bred of thought for the good of the science, endeavoured, in the application of the rule, to carry back to Virgil, Catullus, and other classical writers the scientific nomenclature of plants. But the event which most roused the attention of European botanists was the publication, in 1891, by Otto Kuntze, of his "Revisio generum plantarum"—a book remarkable no less for the industry and linguistic powers it exhibits than for its audacity and unconscious humour. Having assumed the *rôle* of a reformer of nomenclature, the author begins business by changing the names of some thousand genera and thirty thousand species, the new ones being only certified by the coincidently significant initials O. K.! As a curiosity of botanical literature the book will be historical; meanwhile its menace to systematic botany has had the effect of drawing from the Berlin school of systematists, which in recent years has shown so much activity, a statement of views which, after circulation, was submitted to the meeting of botanists at Genoa in 1892.

If the result of all the discussion and conference that has taken place has not been the establishment of a common agreement, they have at least served to bring out the points of divergence of view. We cannot, of course, discuss here the various issues upon which botanists are disagreed on this subject, but we may point out that the differences are mainly upon the starting point of nomenclature and the import of the specific name. The German school, which appears to carry with it a considerable bulk of continental opinion, prefers 1753 as the starting point for both genera and species to the date adopted in the Index, but makes an important declaration of adhesion to the principle of

expediency as qualifying the strict priority rule. The Americans have come round to fix 1753 as the starting point of nomenclature, but unfortunately tack on to the priority rule a rider compelling the use of the earliest specific apellation wherever the genus is changed—a proper enough rule if botanists would only follow it, but which, if carried out retrospectively, as they propose, would involve a changing of plant names appalling to contemplate.

We have said sufficient to show the importance of the "Index Kewensis," and to make clear that its issue at this time is most opportune. The professed desire of all systematic botanists—although there is a wide gulf often betwixt their profession and their practice—is the establishing of a stable nomenclature. To this end the "Index Kewensis" is the most important contribution that has appeared since the "Genera Plantarum" of Bentham and Hooker was completed, and it supplements that work. What effect it will have in bringing about a modification of the views now held by continental and American botanists time will show. In the various discussions and conferences through which it has been attempted to settle questions of nomenclature, the Kew botanists have not taken active part; they have done better, and in the "Genera Plantarum," and now in this "Index Kewensis," we have practical expression of their views, and systematic botanical literature is enriched with what may be fairly termed the most valuable and important additions of the century. The "Index Kewensis" provides a book of reference which every library must possess, and there need be little doubt its nomenclature will take firm hold in this country at least.

For the detail and workmanship in the book we have nothing but praise. They are of a kind we are in the habit of associating with the race which has given us "the sausage for food and the encyclopædia for knowledge," but the book shows there is no monopoly in this sort of work. It is a lasting tribute to the painstaking industry, skill, and knowledge of Mr. Daydon Jackson. The citation of the place of first publication of a species is a most valuable feature in the book, supplying at once a clue through which its history may be followed, and the mention of the native country, necessarily general and brief in most instances, is a further helpful feature. We could have wished for a more extensive citation of the garden names of plants; in every-day life these are constantly turning up, and of no names is the history more difficult to run down. In a work such as this, the preparation of which has taken so many years, and the separate items of which are so multitudinous, slips, omissions, and inconsistencies must occur; but the number of these, so far as use has enabled us to judge, is remarkably small. "Menda non commemorata lector benevolens ipse corriget," says Mr. Daydon Jackson, as a preface to a list of "addenda et corrigenda" in each fasciculus; let us hope readers will also send them to Mr. Daydon Jackson, who may incorporate them in succeeding fasciculi.

It only remains to add, regarding the style and printing of the book, that the best work of the Clarendon Press is displayed in it.

ASTRONOMY FOR THE PUBLIC.

In the High Heavens. By Sir Robert S. Ball, F.R.S. (London: Isbister and Co., 1893.)

IT is not too much to say that at the present time Sir Robert Ball is the fashionable interpreter of astronomical science. He retails to the general public, by voice and by pen, the facts accumulated by astronomers who love their science for her own sake, the practical observer and the eloquent expositor thus mutually benefiting one another.

The book before us contains a collection of heterogeneous articles, several of which have appeared in the *Contemporary* and *Fortnightly*, and all of which are written in the style that pertains to magazines. To the student of science this diffuse method of expounding facts is distasteful. As Ruskin has remarked, "A downright fact may be told in a plain way; and we want downright facts at present more than anything else." The chapter on "The 'Heat Wave' of 1892" furnishes an example of what can be done in the way of connecting facts between which there is apparently no relation. The chapter begins with a description of the temperature observations in different parts of the world in July and August, 1892; it then passes to the movements of the moon, transits of Venus, and meteor-showers, in illustration of the accuracy of astronomical predictions as against the prediction of weather. The work of Lord Kelvin and Prof. G. H. Darwin on tidal prediction is next considered, and the tide-predicting machine of the former is described. Fourier's theorem is discussed, and some of the causes affecting the heights of tides mentioned, the chapter finally concluding with an account of Prof. Hale's photographs of a luminous eruption on the sun in July, 1892. The different scraps of information in this *omnium gatherum* are joined together with an ingenuity that is only acquired after long practice; but in spite of this, the article gives one the impression that the author has spun out his subject in order to provide copy.

The star 1830 Groombridge is a "King Charles' Head" to Sir Robert Ball, the reason being its large proper motion. We doubt whether he has ever written a book in which the number of miles per second, per minute, per hour, per day, per annum, &c. through which 1830 Groombridge travels, is not enlarged upon; and in the volume under review this runaway star is twice inflicted upon the reader. So persistently, indeed, does 1830 Goombridge appear, that we begin to wonder whether it is hurrying through space at a great rate in order to afford subject-matter for popular lecturers and writers on astronomy.

Another subject that has often given Sir Robert Ball an opportunity of exercising his descriptive faculty is the correlation between solar and terrestrial phenomena. But in view of the facts recently brought out in these columns and elsewhere, he may find it necessary to modify or substantiate the statement that "great outbursts on the sun have been immediately followed, I might almost say accompanied, by remarkable magnetic disturbances on the earth."

For the sake of historical accuracy, it may be well to

point out that Prof. Rowland first made the striking remark that "were the whole earth heated to the temperature of the sun, its spectrum would probably resemble that of the sun very closely" (*Johns Hopkins University Circular*, No. 85, February, 1891). In referring to Prof. Rowland's work in August, 1891, at the British Association meeting of that year, Dr. Huggins made practically the same remark, and Sir Robert Ball (p. 169) quotes his words, and gives him the credit for the idea they contain.

Two of the chapters in the book refer to shooting-stars, meteors, and meteorites; and in them the author discusses the origin of meteorites and the relation between meteorites and comets. In his opinion, meteorites are masses of matter ejected from terrestrial volcanoes in a primeval condition of the earth; but we fancy that the analyses of most meteorites do not favour this origin. How, for instance, is the absence of quartz accounted for? But, as a matter of fact, Sir Robert Ball is almost the only astronomer who holds the volcanic view, and the same can be said with regard to his denial of the connection between comets and meteorites, and between meteorites and shooting-stars. The work of Schiaparelli and Newton, Tisserand, and Schulhoff, not to mention many others, considerably outweighs all that Sir Robert Ball has ever said upon the matter. The spectroscopic evidence upon the connection is dismissed in half a dozen lines, while page upon page is devoted to a description of what might happen to masses of matter projected from the moon or a minor planet. In fact, by discussing and judging these theories in a volume designed for the general reader, Sir Robert Ball has made a mistake. Though he has done some excellent mathematical work, astronomers are not at all ready to recognise him as a judge on matters of astronomical physics. His function is to expound and popularise discoveries in celestial science, and when he is exercising it he is at his best.

There are some good points about the book, and anyone desirous of obtaining information upon a few of the recent important discoveries in astronomy will profit by reading it. The illustrations are not so numerous as they ought to be, but what are included are mostly very good, though the illustration on p. 156, of the region of the Milky Way about β Cygni, should have been a positive instead of a negative, for in its present form it looks more like a pathological section than anything else.

It would be an advantage if, in a future edition, the author would give the name of the observer of the solar eruptions figured on pp. 271, 273, 338, and 339. We fancy that Father Fenyi was the original draughtsman of the prominence forms there illustrated, but cannot find his name mentioned in the text relating to them.

R. A. GREGORY.

OUR BOOK SHELF.

Practical Agricultural Chemistry for Elementary Students. By J. Bernard Coleman, A.R.C.Sc., F.I.C., and Frank T. Addyman, B.Sc., F.I.C. (London: Longmans, Green, and Co., 1893.)

"THE course of instruction described in this book has been in use for some years at University College, Nottingham." After a few instructions as to the use of apparatus, there follows a short course of experiments on oxygen, air, carbonic acid, water, and hydrogen. The third section treats experimentally of soils, manures, feeding materials, and dairy produce, and gives a number of simple experiments that serve to show many of the most important properties of these substances. For example, the differences between the sulphur present in gas-lime and in gypsum respectively, and the various conditions in which phosphoric acid occurs in superphosphates, bone phosphates, reverted phosphate, and slag phosphates are made the subjects of experiment. Tests are given for the various constituents of manures. Oilcakes, grass and hay, roots, flour, milk, butter and cheese, are dealt with in a similar manner. The fourth section of the volume gives a few reactions of a select number of metals (viz. seven) and acids, with a few other matters, and tables for the qualitative analysis of substances containing them. We would remark in reference to this, that to allow students to fuse insoluble substances in porcelain crucibles, in order to test for silica, is, to say the least of it, undesirable.

Regarding the volume as a whole, it forms an excellent addition to an ordinary student's course of agriculture, whether this is, as is too often the case, only a matter of listening to a few lectures, or whether practical agriculture forms an essential part of it. Perhaps it is hardly possible for a teacher to take much account of the danger that is proverbially inseparable from a little knowledge; but in cases where this is particularly liable to manifest itself, it may be his duty to do what he can to obviate the evil. Speaking from experience, we fear there are students who, after having worked through these seventy-one pages, would not hesitate to state that they had studied inorganic and organic practical chemistry at whatever college they might have done the work. In this way it is at least possible for grave discredit to be brought undeservedly upon the usual course in chemistry at such a college; for there are many people with no technical knowledge of these matters, who attach considerable value to the mere fact that a specific routine of study has been gone through at a well-known educational establishment. It appears, therefore, to be highly desirable to do whatever may be possible to prevent such a chemical course as that in this volume from being in any way confused with even the most elementary course that is arranged to impart a knowledge of chemistry itself. A similar danger doubtless exists in many other cases, but it may probably be said with truth, that there is in none other likely to be so great a temptation to misrepresent facts by an incomplete statement of the truth.

C. J.

Bionomie des Meeres. Von Johannes Walther. Erster Theil einer Einleitung in die Geologie als historische Wissenschaft. (Jena: Gustav Fischer, 1893.)

PROF. WALTHER has set before himself an ambitious programme, which, if carried out, should result in a geological treatise of great interest; we fear also of portentous length. The first instalment is a modest little book of 200 pages, with a preface summarising the travels and researches which the author made for ten years with a view to fit himself for the task, and a separately paged introduction defining the scope of the contemplated work, and enunciating the ontological method in geology. Bionomy is the study of the life-habits of organisms in relation to their environment, and it is obvious that the bionomy of the ocean at the present time must be the clue to all deductions from the character of marine fossils regarding the physical conditions in which they were produced.

Prof. Walther is extremely systematic, and in twenty numbered sections he summarises a vast amount of recent work on the relation between marine organisms and physical conditions. His numerous references to original memoirs might be profitably increased by the inclusion of more British, French, and American work, and espe-

cially by some indication of such piles of raw material for discussion as have been accumulated by the Fishery Departments of many governments. A compilation of this sort depends for its value on its completeness, as the reason for adopting one theory or classification rather than another must be the outcome of an attempt to weigh evidence. After a brief discussion of the conditions of life, there follow sections on the life-districts of the ocean, Hæckel's classification of marine organisms, a concise discussion of the influence of light, temperature, salinity, tides, waves, and currents on marine life, and a short statement of the flora and fauna of the littoral, shallow water, estuarine, open sea, deep sea, and oceanic archipelago divisions, concluding with a few pages on the geological changes of ocean basins.

It would be premature to express an opinion of Prof. Walther's contemplated work. The sketch he gives of its plan stimulates interest and curiosity, and we can heartily congratulate him on the orderly way in which he has collected and laid down the building-material, while we wish him success in his labours.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Correlation of Solar and Magnetic Phenomena.

THE opinion of Mr. Whipple, quoted at p. 2 of NATURE for November 2, to the effect that the solar outburst observed by Messrs. Carrington and Hodgson on September 1, 1859, was not the cause of the coincident magnetic perturbations, corresponds to my own conclusion in regard to the matter based upon evidence of an altogether different character. There was a recurrence of strong magnetic perturbations and auroras twenty-seven days later than the great magnetic storms of August 28 and September 1, 1859, thus following the general rule which is found to apply in such cases, there being a well-marked periodicity of such outbreaks at this precise interval corresponding to the time of a synodic rotation of the sun. Such recurrence manifestly could not exist if outbreaks upon the sun were able to produce terrestrial magnetic effects indifferently in all locations. In order that there may be recurrence at the synodic period the magnetic effects must proceed from the sun at some particular angle exclusively, and fortuitous outbursts elsewhere, no matter how violent, must fail to have any perceptible effect. In the estimation of the writer there is no point more important in connection with solar physics than the determination of this period and this angle with the greatest accuracy possible.

M. A. VEEDER.

Lyons, N.Y., December 26, 1893.

MY letter in NATURE (vol. xlix. page 30), amongst other interesting communications, has brought one from Mr. Lawrance (vol. xlix. page 101) and the accompanying letter from Dr. Veeder. Mr. Lawrance's graphic account well describes the circumstances attending the manifestation of 1882 (November 17). The magnetic disturbance which broke out at 10 a.m. on that day set us all on the look-out for aurora in the evening. Neither were we disappointed; the display was remarkable. But the question in this case, as with the Carrington-Hodgson and Young instances, is still whether the solar and magnetic phenomena were directly related or simply coincident. This cannot be said to be determined, and nothing less than proof, in so important a matter, will serve. Better to advance surely if slowly towards truth, rather than accept too hastily evidence that is incomplete. We must remember that on the occasion of the solar disturbance seen by Trouvelot, the magnets were especially quiet, not only at the time but also before and after. But any explanation of these phenomena must include all cases. The position of things, as stated in my first letter, referred to above, still I consider holds, qualified only by the circumstance that instead of one presumed case of direct relation, three are now adduced, with a fourth case (the Trouvelot observation), which unquestionably was not accompanied by magnetic disturbance. If we further consider that, since the year 1859, when attention became distinctly drawn to this question, there has occurred magnetic movement, equal to and in very many cases far exceeding that accompanying the Carrington-Hodgson observation, on some 400 different days, we see on how slight a foundation the presumption for direct relation, that is of a nature more or less instantaneous in action, exists, although the general relation between the two classes of phenomena remains undoubted.

Dr. Veeder, from his own point of view, supports the contention that the 1859 solar outburst cannot be taken as causing the accompanying moderate magnetic movement; indeed there was far greater movement some three days previously, and again early on the morning of the following day; but in regard to his affirmation that there exists a well-marked periodicity in magnetic outbursts corresponding to the period of the sun's rotation, whilst this in a limited sense may be in some degree true, I cannot say that my personal acquaintance with magnetic records during very many years enables me at present to accept such conclusion as a general one, or indeed what as a consequence follows, that anything really depends on the position in rotation which the sun occupies relatively to the earth.

The whole subject is, however, exceedingly interesting, and various considerations arise. One bearing on the present question may be mentioned. Great terrestrial magnetic disturbances are evidently in character cosmical, produced, it would seem, or stimulated, by some external cause. For it has been shown (Proc. Roy. Soc. vol. lii. p. 191) that, on occasions of unusually sudden magnetic disturbance, the commencement of disturbance, at places so widely separated on the earth's surface as Greenwich, Pawlowsk, and Bombay, is simultaneous within a much smaller limit of time than had before been supposed. Such sudden simultaneous action would thus appear to indicate an impulse, solar or otherwise, from without, but whether one distinctly solar, or in what other way produced, is a question yet to be determined.

WILLIAM ELLIS.

Greenwich, January 6.

The Mendip Earthquake of December 30-31, 1893.

I SUBMIT the following notes for the use of any of your readers who may be collecting information on the subject:—

So far as I can judge, from statements obtained directly from inhabitants of the locality, and from the experiences of various persons, recorded in the *Shepton Mallet Journal* of January 5, the movements in this earthquake occurred chiefly along the south flank of the Mendip Hills between Shepton Mallet on the east-south-east, and Draycott (near Cheddar) on the west-north-west. The shock extended as far southwards as Evercreech and West Pennard; it reached as high up as Priddy, which is near the axis of the hills, and was also noticed at Chewton, several miles distant on the northern flank.

The force of the shocks appears to have been very irregularly distributed, in some houses the movements being quite alarming, while in others not far distant they were trifling though unmistakable. Some persons failed to hear the sound, which was very evident to others. Persons out of doors heard the sound most distinctly, even when they felt no shock.

A lady at Shepton Mallet, who had previously experienced an earthquake in New Zealand, recognised at once what was occurring, but was not in any way alarmed. She says that her bed began suddenly to shake or rock, and as suddenly ceased. She was also conscious of a movement of the whole house, and in the sharper shock heard the furniture rattle; but she did not observe any rumbling. Another lady in the same house noticed particularly the "funny unusual sort of noise." Again, in the same house a man describes the movement as resembling a wave moving from east to west. A school master and mistress got up under the impression that the water-heating apparatus had burst. At West Compton a lady in a farmhouse thought from the sound and movement "that some one was about the house, or that a barrel of cider had burst." At Westbury-below-Wells the shock was sharp enough to cause alarm.

The policeman on duty at Shepton Mallet very naturally referred the sound to the direction of the Midland Railway, which runs high on the hills in such a way that the rumble of its trains is heard at a great distance. It is well known that we have but little certainty in localising sounds, especially if of indefinite character, and that we usually refer them to positions whence we expect them.

The area in which the earth-movements seem to have been

most felt, corresponds with a series of outlying masses of carboniferous limestone, which are separate from the main mass of carboniferous limestone of the Mendip anticlinal. Whether these are parts of another anticlinal, or owe their position to faulting, I do not know. Westward of Wells these outliers form little knolls, as at Draycott and Westbury. Further east, in the area between Wells, Shepton Mallet, and West Compton, they form a group of prominent hills, whose valleys are occupied by later formations. If such outliers exist east of Shepton Mallet, they are deeply hidden by the oolitic strata.

Evercreech and West Pennard lie off this carboniferous limestone, but it extends beneath the valley in which these villages lie. Priddy is on the main anticlinal of the Priddy Mendip hills, and Chewton is separated from all the foregoing by the exposure of Old Red Sandstone. It would be interesting to know how far the Old Red Sandstone shared the movements; but information is likely to be scanty, as the sandstone forms a bleak and sparsely inhabited region. F. J. Allen.

Mason College, Birmingham, January 6.

Quaternionic Innovations.

That Prof. Tait should not be able to do justice to those who prefer to treat vectors as vectors, and quaternions as quaternions, instead of commingling their diverse natures, with the result, in the latter case, of confusion of physical ideas (and geometrical also, for of course geometry is itself ultimately a physical science, having an experiential foundation), is naturally to be expected. He does not know their ways, either of thinking or of working, as is abundantly evident in all that he has written adversely to Prof. Willard Gibbs and others. It is, however, a little strange, in view of Prof. Tait's often expressed conservatism regarding Quaternionics, that he should tolerate *any* innovations therein, such as Mr. MacAulay has introduced. The latter may perhaps take this as a compliment to his analytical powers, which compel the former's admiration, and toleration of his departures from quaternionic usage. For myself, I welcome any quaternionic innovations that may (ultimately) tend in the direction of the standpoint assumed by Prof. Gibbs and others, and foresaw some two years since (when a very bulky manuscript came to me for my opinion) that there would be some quaternionic upstirring.

Prof. Gibbs has already pointed out how the development of Quaternionics has involved first the elimination of the imaginary, and next the gradual elimination of the quaternion! Now there is a capital illustration of this innate tendency in Prof. Tait's review (Nature, December 28, 1893), where, on p. 194, he explains by an example the meaning of a startling innovation of Mr. MacAulay's. Put it, however, in vectorial form, and let us see what it comes to then. Take the case of a stress and the force to correspond (which is a little easier than Prof. Tait's example, though not essentially different). Let ϕ be a stress operator (pure, for simplicity), so that $\phi\mathbf{N}$, or $\mathbf{N}\phi$, is the stress per unit area on the $\mathbf{N}$ plane, $\mathbf{N}$ being any unit vector. Now we know, by consideration of the stresses acting upon the faces of a unit cube, that the $\mathbf{N}$ component of the force $\mathbf{F}$ per unit volume is the divergence of the stress vector for the $\mathbf{N}$ planes. That is,

$$\mathbf{FN} = \nabla\phi\mathbf{N}, \qquad (1)$$

for any direction of $\mathbf{N}$. I employ my usual notation for the benefit of readers (now becoming numerous) who, though they cannot follow the obscure quaternionic processes, can understand the plainer ones of pure vector algebra. Now, may we remove the vector $\mathbf{N}$ (which is any one of an infinite number of vectors) and write

$$\mathbf{F} = \nabla\phi \text{ or } = \phi\nabla \qquad (2)$$

simply, as the complete expression for the force? Certainly we may. For, in full, we have

$$\nabla = \mathbf{i}\nabla_1 + \mathbf{j}\nabla_2 + \mathbf{k}\nabla_3, \qquad (3)$$

$$\phi = \phi_1.\mathbf{i} + \phi_2.\mathbf{j} + \phi_3.\mathbf{k} \text{ or } = \mathbf{i}.\phi_1 + \mathbf{j}.\phi_2 + \mathbf{k}.\phi_3, \qquad (4)$$

where ∇_1, &c. are the scalar components of the vector ∇ (not a quaternion, of course) and ϕ_1, &c. are the vector stresses on the planes of $\mathbf{i}$, &c., so that $\phi_1 = \phi\mathbf{i}$, &c. Direct multiplication gives at once

$$\nabla\phi = \nabla_1\phi_1 + \nabla_2\phi_2 + \nabla_3\phi_3, \qquad (5)$$

which is $\mathbf{F}$. We may also write it $\phi\nabla$, because ϕ is pure.

On the other hand, when ϕ is rotational, let its conjugate be ϕ', then instead of (1) we have

$$\mathbf{FN} = \nabla\phi'\mathbf{N}, \qquad (6)$$

and therefore

$$\mathbf{F} = \nabla\phi' = \phi\nabla. \qquad (7)$$

Here if ϕ is given by the first expansion in (4), ϕ' is given by the second.

Now there are several things that deserve to be pointed out about the above, which should be compared with Prof. Tait on p. 194. First, that the result $\mathbf{F} = \phi\nabla$, irrespective of pureness, or $\mathbf{F} = \nabla\phi$ also when the stress is pure, when got quaternionically seems to be a great novelty to Prof. Tait, and to give him a "severe wrench," involving a "dislocation" and a "startling innovation." Perhaps, however, it is only Mr. Macaulay's peculiar way of arriving at the result, that Prof. Tait is alluding to. Moreover, secondly, in the vector algebra of Willard Gibbs and others the use of equation (2) or of (7) to express the force complete, by removal of the intermediate vector $\mathbf{N}$, is neither new, nor does it involve any straining of the intellect, for it is actually a part of the system itself, done naturally and in harmony with Cartesian mathematics. See Gibbs's "Elements of Vector Analysis" (1881–4) for the direct product of ∇ and ϕ. (Also for the skew product, a more advanced idea; it, too, is a physically useful result.) Thirdly, note how very differently the same thing presents itself to Prof. Tait according as it is clothed in his favourite quaternionic garb or in vectorial vestments. In the latter case it is either unnoticed or is contemptible; in the former, it may be a novel and valuable improvement.

I do not think that Prof. Tait does justice to Mr. MacAulay in making so much of a trifle such as passes unnoticed or unappreciated in the previous work of others. There is, I know, much more in Mr. MacAulay's mathematics than Prof. Tait has yet fathomed. For my own part, I like to translate it into vectors, not merely because it is then in a form I am used to, and is plainer, but also because the true inwardness of these processes involving linear operators is properly exhibited by the dyadical way of viewing them in conjunction with vectors, without the forced and unnatural amalgamation with quaternions, and the attendant obscurities. This seems to me to be particularly true in physical applications. I should not be writing this note were it not for the misconceptions that Prof. Tait indulges in about what he does not know, viz. vector algebra apart from quaternions. At the same time, to avoid possible misunderstanding, I disclaim any hostility to Mr. MacAulay's quaternionic innovations, although I must agree with Prof. Tait as to the "singular uncouthness" of some of his expressions in their present form. I hope he may be able to see his way to do his work vectorially. It will be more amenable to innovations, I think, without mental wrenches. At any rate he is a reformer, and not afraid to innovate when he thinks fit.

Oliver Heaviside.

Paignton, Devon, December 30, 1893.

The Second Law of Thermodynamics.

I apologise to Mr. Bryan for unintentionally reading into the Report, Article 17, what he did not intend to be there. I understand now that according to his view conservative systems are not alone to be included in the Clausian proof.

My point, however, is (or was) that they ought to be excluded, at all events when there is only one controllable coordinate v, because (1) in conservative systems the virial equation gives a relation between T and v, so that only one of them is independent. That, I submit, is true in fact. And (2) the second law, I said, requires two independent variables. That, however, is a question of definition, and if Mr. Bryan were to take the equation

$$\int\frac{\partial Q}{T} = 0$$

for a complete cycle, whatever be the nature of the system, as a definition of the second law, I see no valid objection to that definition.

I admit, and did admit, that for a conservative system, moving in a complete cycle,

$$\int\frac{\partial Q}{T} = 0,$$

and therefore I admit that if Mr. Bryan attaches his wheel and windlass to my pistin of constant mass, we should get

$$\int \frac{\partial Q}{T} = 0$$

for each complete turn of the wheel. Whether that equation can be correctly said to express the second law, where there is only one independent variable, is a question of definition of the second law.

I said, also, that if we are at liberty to vary the mass of the pistin, we have two independent variables, but no longer a conservative system. Mr. Bryan, with greater generality, points out that the same effect would be produced by altering the gravitation-potential.

The objections to Clausius's proof generally cannot be more forcibly stated than they are in the Report. What is required is a definition of the time "i." The absence of that definition is to my mind not only an objection, but a quite fatal objection. If, as I proposed, we make

$$i = \frac{v^2}{T^2},$$

that answers the purpose for the very limited class of cases in which

$$\partial\bar{\chi} = \overline{\frac{d\chi}{dv}}\partial v.$$

A treatment of the subject in generalised coordinates is as follows:—Let $y_1 \ldots y_n$ be the unconstrainable, $q_1 \ldots q_r$ the controllable coordinates, concerning which latter I assume, as does Boltzmann, that $\dot{q}$ or $\frac{dq}{dt}$, and also $\frac{d^2q}{dt^2}$ are to be neglected. Let χ be the potential, τ the kinetic energy, T the mean value of τ. Then we have generally

$$\frac{\partial Q}{T} = \partial \log T + \frac{1}{T}\left\{\partial\chi + \Sigma\left(\frac{dt}{dq} - \overline{\frac{d\chi}{dq}}\right)dq\right\}.$$

In some cases the term $\frac{dT}{dq}$ does not appear, and therefore in this class of cases

$$\frac{\partial Q}{T} = \partial \log T + \frac{1}{T}\left(\partial\bar{\chi} - \Sigma\overline{\frac{d\chi}{dq}}dq\right).$$

Now let $f dy_1 \ldots dy_n$ be the chance that in the stationary motion with the q's constant, the coordinates shall lie between the limits y_1 and $y_1 + dy_1$, &c., so that

$$\bar{\chi} = \iint \ldots \chi f dy_1 \ldots dy_n$$

and

$$\overline{\frac{d\chi}{dq}} = \iint \ldots \frac{d\chi}{dq} f dy_1 \ldots dy_n.$$

This makes

$$\partial\bar{\chi} - \Sigma\overline{\frac{d\chi}{dq}}\partial q = \iint \ldots \chi\partial f dy_1 \ldots dy_n,$$

and

$$\frac{\partial Q}{T} = \partial \log T + \iint \ldots \frac{\chi}{T}\partial f dy_1 \ldots dy_n.$$

In order that $\frac{\partial Q}{T}$ may be a complete differential, we must make $f = \phi\left(\frac{\chi}{T}\right)$, where ϕ is an arbitrary function. That is the general solution.

Now it will be found that this general solution agrees exactly with that given by Mr. Nichols. For his condition is

$$\frac{1}{T}\left(\frac{d}{dv}\bar{\chi} - \overline{\frac{d\chi}{dv}}\right) = -\frac{d}{dT}\overline{\frac{d\chi}{dv}}.$$

Now the use of these averages necessarily implies the existence of a function f, such that

$$\bar{\chi} = \int f\chi d\sigma, \quad \overline{\frac{d\chi}{dv}} = \int f\frac{d\chi}{dv}d\sigma,$$

the integrations being with proper coordinates, and therefore

$$\frac{d}{dv}\bar{\chi} - \overline{\frac{d\chi}{dv}} = \int \chi\frac{df}{dv}d\sigma.$$

Mr. Nichols' condition may therefore, without loss of its generality, be put in the form

$$\int \frac{\chi}{T}\frac{df}{dv}d\sigma = -\int\frac{d\chi}{dv}\frac{df}{dT}d\sigma.$$

The general solution of this is

$$f = \phi\left(\frac{\chi}{T}\right),$$

as before

That equation,

$$f = \phi\left(\frac{\chi}{T}\right),$$

seems to me to define the limits of the second law for all cases in which the term $\frac{dT}{dq}$ does not appear in Lagrange's equations.

I hope if Mr. Bryan comes to discuss the virial proof, he will give his opinion on this point.

I think that the term $\frac{1}{T}\frac{d\tau}{dq}$, when it exists, can be made to lead to a somewhat similar condition. If, namely, F be the chance of a given combination of the velocities,

$$\frac{1}{T}\overline{\frac{d\tau}{dq}} = \int\frac{F}{T}\frac{d\tau}{dq}d\sigma = -\int\frac{\tau}{T}\frac{dF}{dq}d\sigma$$

$$= -\int\frac{\tau}{T}\partial F d\sigma + \partial \log T,$$

whence F must be a function of $\frac{\tau}{T}$.

I have to thank Mr. Bryan for reminding me of Mr. Nichols' paper, which I had forgotten, though I had some discussion with its author at the time. S. H. Burbury.

The Fauna of the Victoria Regia Tank in the Botanical Gardens.

Prof. Lankester's account of the "Freshwater Medusa," in Nature, December 7, 1893, shows how with very little trouble the interests of zoologists may be served by those who have the charge of botanical gardens like that in the Regent's Park. All that is necessary is to refrain from periodically cleaning out the tanks in which tropical water plants are grown. When these latter are imported from abroad they often carry with them various aquatic animals of novelty or interest like the medusa mentioned. This particular tank has recently produced quite a number of remarkable animals. Mr. Bousfield, some years since, found certain new or little known species of *Dero* therein, and more recently Prof. A. G. Bourne met with a new form of the Naid genus *Pristina* in the same tank. I have been able, thanks to the courtesy of Mr. Sowerby, to examine water and decaying weed therefrom on more than one occasion, and I discovered a series of rare or novel species of *Oligochæta*. The most remarkable form was one which I described a year or two since as a new genus *Branchiura*; this worm, with the general characters of a *Tubifex*, possesses a row of dorsal and ventral branchial processes, besides showing other points of interest. In the same sample of water were large quantities of a Naid, called by its original describer, Prof. Bourne, who met with it in the town of Calcutta, *Chætobranchus semperi*. This worm has also a series of branchiæ, but they are lateral in position, and enclose the long dorsal setæ of the Annelid, thus suggesting the parapodia of the marine Chætopods. I have also found the rare species *Æolosoma niveum* in the same locality, and a freshwater Nemertine (♀ *Tetrastermma aquarum dulcium*), besides a number of Oligochæta which I did not at the time identify.

Frank E. Beddard.

Rudimentary (Vestigial) Organs.

Prof. Hartog's letter in your issue of the 28th ult. is interesting as an illustration of the extreme danger of regarding an organ as vestigial and functionless merely because our superficial investigations have not revealed to us its use.

If Prof. Hartog had examined the distal knob of the modern eyeglass, even by the old-fashioned macroscopic methods, he would have seen that there passes through a screw, whose function is to hold the two sides of the oval frame together, and thus retain the lens in place.

The knob is also useful as a convenient point to lay hold of

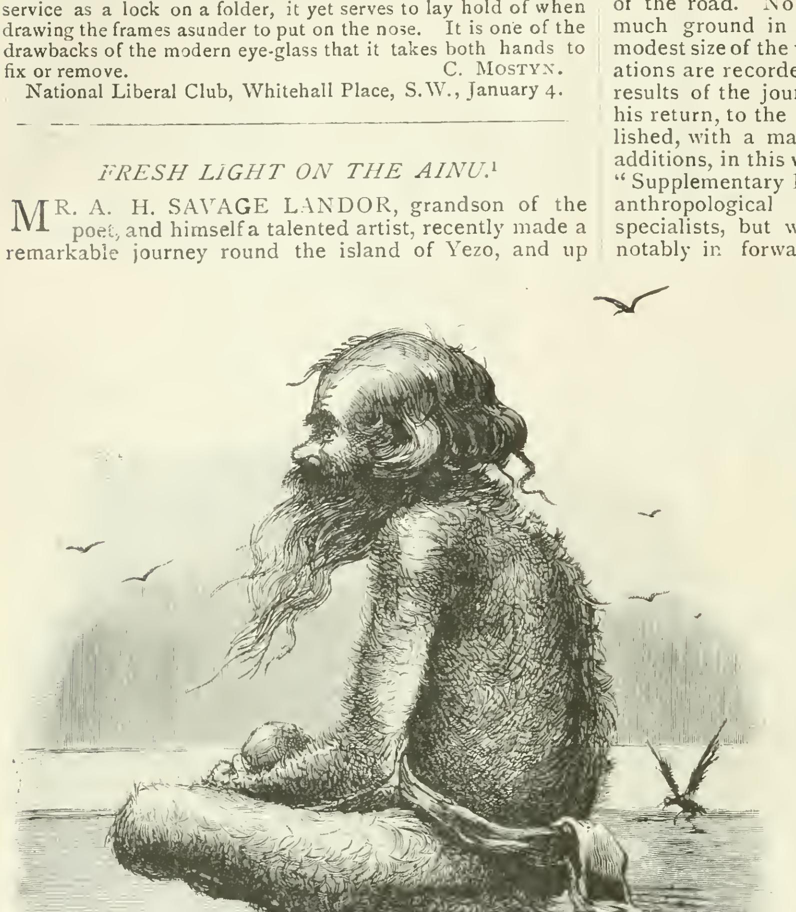
in drawing the two lenses apart. We may, I think, prophesy that these two functions will secure the orga n against disappearance. W. E. H.

ALLOW me, as a wearer of the modern style double eye-glass, to point out to Prof. Marcus Hartog that the knob on the distal frame owes its survival to its utility. Though no longer of service as a lock on a folder, it yet serves to lay hold of when drawing the frames asunder to put on the nose. It is one of the drawbacks of the modern eye-glass that it takes both hands to fix or remove. C. MOSTYN.

National Liberal Club, Whitehall Place, S.W., January 4.

FRESH LIGHT ON THE AINU.[1]

MR. A. H. SAVAGE LANDOR, grandson of the poet, and himself a talented artist, recently made a remarkable journey round the island of Yezo, and up many of its large rivers, repeating Captain Blakiston's route in 1869 so far as regards the north-east and west coasts, but supplementing that traveller's journey along the whole east coast and in the interior. He travelled alone, with practically no equipment except for painting; and during five months he lived almost exclusively with the Ainu, even sharing their food. He visited in this way nearly every native village in Yezo, and estimates the total number of pure-bred Ainu now on the island at about 8000, while the Japanese estimate of the whole Ainu population, including half-breeds, is from 15,000 to 17,000. Mr. Landor gives a lively and straightforward account of his journey, illustrated by numerous portraits, pieces of landscape, and drawings of houses and implements, which is replete with incidental information as to the ways of the primitive people and the minor adventures of the road. No European has previously covered so much ground in Yezo, and we are surprised at the modest size of the volume in which so many fresh observations are recorded for the first time. The geographical results of the journey were communicated, shortly after his return, to the Royal Geographical Society, and published, with a map of the island (reproduced, with some additions, in this volume), in the last part of the Society's "Supplementary Papers." We are not aware that the anthropological data have yet been submitted to specialists, but we feel confident that they will assist notably in forwarding our knowledge of the difficult problems of Ainu ethnology. The author as an artist has a keen and discriminating eye for form and colour, so that his observations carry much more weight than the chance remarks of most non-scientific travellers. It seems a pity that some of the portraits are not reproduced in colour, and we trust that an effort will be made to secure for anthropological collections some of the original pictures, which we understand are still in Mr. Landor's possession.



In the course of the narrative a chapter is inserted on the Koro-pok-kuru, or early pit-dwellers, the supposed aborigines of Yezo; ten chapters at the end are devoted to Ainu architecture, art, and graves, Ainu heads and their physiognomy, movements and attitudes, clothes, ornaments and tattooing, music, poetry and dancing, heredity, crosses, psychological observations, physiological observations, pulse-beat and respiration, odour of the Ainu, the five senses, superstitions, morals, laws and punishments, marital relations and the causes that limit population.

These and an appendix giving measurements of the Ainu body constitute a definite addition to science, which loses but little of its value through being expressed in popular language. Indeed, it is a matter of some importance that such facts should be disseminated by a book which, altogether apart from its intrinsic value, will be widely read on account of its fascinating human interest.

The illustrations which we reproduce are extremely characteristic portraits, showing admirably the hairy character of the men, and the well-known fashion of tattooing a moustache on the women.

The average measurements of ten pure Ainu (five men and five women) of Frishikobets, on the upper Tokachi river, were as follows:—Height, $62\frac{1}{2}$ inches for men, $58\frac{3}{8}$ inches for women; length from tip to tip of fingers with arms outstretched, $65\frac{3}{8}$ inches for men, $61\frac{1}{4}$ inches for women; chest measurement, $37\frac{1}{10}$ for men, $34\frac{1}{5}$ for women. The pure Ainu physiognomy is described as follows:—"When seen full-face the forehead is narrow and sharply sloped backward, the cheek-bones are prominent, and the nose is hooked, slightly flattened, and broad, with wide, strong nostrils. The mouth is generally

[1] "Alone with the Hairy Ainu; or, 3800 Miles on a Pack Saddle in Yezo, and a Cruise to the Kurile Islands." By A. H. Savage Landor. (London: John Murray, 1893.)

large, with thick, firm lips, and the underlip well developed. The space from the nose to the mouth is extremely long, while the chin, which is rather round, is comparatively short and not very prominent. Thus the face has the shape of a short oval. The profile is concave, and the mouth and eyebrows are prominent . . . . In the supraorbital region the central boss is extremely well marked; also the brow ridges, which, however, are slightly less conspicuous than the central boss. The ears are usually large, flat, and simply-developed." Mr. Landor shows, by a series of detailed contrasts, that the pure Ainu has no similarity whatever to the Mongolian type. The colour of the skin he found to be light reddish brown. The eye is particularly contrasted to the Mongolian eye, having a similar form and setting to that of North Europeans, while the iris is light brown or dark grey—rarely black or dark brown, except in the case of half-breeds. The eyes are very expressive, and show the emotions in an interesting way. In adults the hair is black, wavy, and inclined to form large curls; children have lighter hair, and in the north-east of Yezo several men were seen with reddish hair and beard. Mr. Landor never saw the

pure Ainu laugh, though on one occasion he induced a man to "roar" with surprise and delight. The various emotions are expressed by slight changes of posture or gesture, but the Ainu do not care to show their feelings; they have no sense of shame, and even fear appears hardly to be known.

The women do most of the hard work, but the men when hunting can walk forty miles a day without fatigue, although they usually prefer to ride, ponies being plentiful and of a good breed. In moving a load or heavy object the Ainu never push, but always pull towards them. They appear to use the feet and toes very freely to help their hands and fingers, and they readily employ their teeth, preferring to pull with the teeth than the hand when an unusually heavy haul is necessary. The whole appearance struck Mr. Landor as exactly like the reconstructions of the primitive man of northern Europe, and many of their movements recalled those of the anthropoid apes.

In sexual matters the Ainu appear to have no definite rules, but a form of endogamy is common, which scarcely differs from promiscuity. The people are extremely filthy, both in their persons and in their huts, the prevalence of insect parasites being remarkable. They seem to have an acute sense of smell, distinguishing between the odour of an Englishman and a Japanese, but oblivious to their own very marked perfume—an intensified form of the "peculiar odour of an uncleaned monkey's cage." The sense of touch is singularly defective, and even when the extremes are painful, they cannot distinguish the sensation of heat from that of cold. Their hearing is very acute.

Mr. Landor is severe on those writers whose imperfect acquaintance with the Japanese half-castes on the southern coast has led them to theorise on Ainu religion. He acknowledges only "a rudimentary kind of totemism" in connection with the bear festivals, and "a certain amount of fear and respect for anything that supports their life or can destroy it."

In every respect the new observations now published make the Ainu appear to be the most primitive of primitive races in the northern hemisphere. The author brings forward reasons which led him to believe that the Ainu, coming from the north of Asia, and possibly of the same stock as the North Europeans, conquered and dispossessed the Koro-pok-kuru who had come to Yezo from the Aleutian Islands and were akin to the Eskimo.

H. R. M.

THE PURIFICATION OF SEWAGE BY BACTERIA.[1]

THE diffusion of bacteriological knowledge amongst the general public is already beginning to affect the patent list, and numerous inventions which the world is at present asked to take advantage of claim to have some special efficacy in regard to micro-organisms. The pamphlet before us is intended to introduce to public notice one of these bacteriological inventions in a field which has already exercised the ingenuity of many inventors—both professional and amateur—viz., the purification of sewage. In this case the invention is called the "cultivation filter-bed," and the inventor is Mr. Scott Moncrieff, whilst the investigation of its efficiency has been made by Dr. A. C. Houston. The new process of treatment consists essentially in passing the sewage upwards through a filtering medium 14 inches in depth, and composed of successive layers of flint, coke, and gravel. To quote the words of the report, "the *rationale* of this system of sewage disposal seems to depend on the following well-recognised truths:—

"1. That bacteria under favourable conditions are capable of indefinite multiplication.

"2. That bacteria exist in sewage which are capable of peptonising solid organic matter, or, in other words, of preparing it, by a process comparable to that of digestion, for its final disintegration.

"3. That in nature the purification of the refuse of the organic world is effected by the life-history of these or similar micro-organisms."

Having thus learnt what the nature of the method of treatment is—viz. upward filtration without aëration, or, in other words, putrefaction, we turn in the next instance for information as to the effect of this treatment. The report contains a number of analytical tables, but not one of the analyses shows us the composition of the crude sewage, and consequently the numerous analyses of the effluent furnish no data whatsoever as to the purification effected. Turning to the analyses of the effluent, however, we are not surprised to learn that it has generally an unpleasant odour, whilst the albuminoid ammonia in an average sample was 1·1 part per 100,000; but why this should be regarded as "very small," we are

[1] "Report upon the Scott Moncrieff System for the Bacteriological Purification of Sewage." By Alex. C. Houston, M.B., D.Sc. Edin. (London: Waterlow Bros., 1893.)

at a loss to discover. Nor was even the inventor apparently satisfied, for we are told in the report that "in order to still further improve the quality of the effluent by longitudinal filtration, by oxidation, and by the action of micro-organisms, Mr. Scott Moncrieff devised what he has termed nitrifying channels. These in their simplest form consist of half-channel pipes joined together with cement and filled with coke." These channels were originally 30 feet in length, but subsequently they were increased to 80 feet. As regards the efficiency, or rather inefficiency of these channels, we are able to form an opinion from analyses given on pp. 19 and 20 of the report; from these it appears that the free ammonia *before* was 3·2 parts per 100,000, and *after* passing through the 80 feet channel 3·6 parts, whilst the albuminoid ammonia was ·8 part *before*, and ·64 part *after*, respectively, whilst in no case was more than a very small proportion of nitrate discovered in this effluent, showing that these channels are "nitrifying" in name only.

If we now inquire into the machinery involved in producing these results, we find that for a household of ten to twelve persons, the filter-bed was 10 feet long by 2½ feet wide, or 25 square feet in area, whilst the so called nitrifying channel superadded to this was 80 feet in length (the diameter of these channels is not given). For a population of 1000 persons, therefore, a filter-bed, upwards of 2000 feet square, and a nitrifying channel, between 6000 and 7000 feet in length, would be necessary.

It is difficult to discover what claim to novelty Mr. Moncrieff's system possesses; the upward filtration of sewage was practised years ago, and has been generally abandoned on account of the far superior results obtained by downward intermittent filtration. As regards the nitrifying channels, these are simply downward filters of a very clumsy and expensive form, the inefficiency of which is attested by the analyses published in the report. One novelty indeed there is in Mr. Moncrieff's filters, to which they doubtless owe their "up-to-date" title of "cultivation filter-beds," for we are informed that when a new filter-bed is started it is "inoculated" with the liquid contents of an old one! As already pointed out, in the absence of any analyses of the raw sewage, the report gives us no information as to the work really done by the "cultivation filter-bed," but the effluent coming from it certainly contrasts very unfavourably with good effluents obtained either by filtration, irrigation, or chemical precipitation; as regards the work done by the "nitrifying channels," the analyses demonstrate this to be simply deplorable.

In conclusion, we would remark that the chemical analyses might advantageously have been made more complete, so as to render the figures comparable with those given in the best investigations on the purification of sewage; and we would point out that an analysis is not rendered more exhaustive either by expressing each determination in parts per 100,000 as well as in grains per gallon, or by drawing out the results in elaborate but meaningless curves of divers colours.

ARTHUR MILNES MARSHALL.

A GLOOM has been cast over the opening year by the news of what can only be described as a national calamity. Like his friend, Prof. F. M. Balfour, Milnes Marshall has been cut off in the midst of a life of scientific usefulness by an accident among the mountains which he loved. On the last day of 1893 Prof. Marshall, with several companions, started from the hotel at Wasdale Head for a day's climbing among the precipices of Scawfell. All the dangers and difficulties had been passed, and the party were looking for suitable views to photograph. Dr. Marshall had mounted a few feet higher than the others, and called out, "Here is the best place for the camera," when almost immediately a large stone was seen to fall, followed by his apparently lifeless body. The precise details of the mishap will never be known—whether he stepped or sat down upon a rock loosened by the frost, or whether, as is thought by some well qualified to judge to be more likely, a stone fell upon him from above—must remain a matter for conjecture. The melancholy fact is sufficient that a young and brilliant student of nature passed in an instant from the full enjoyment of health and strength to the "cold obstruction" of death.

Arthur Milnes Marshall was born in 1852, and inherited a love of natural science from his father, a gentleman well known in engineering circles, as well as an enthusiastic naturalist and a microscopist of no mean reputation. He was educated first at a private school, and in 1871 entered St. John's College, Cambridge, where he was one of the earliest students of that school of biology of which he afterwards became so distinguished an ornament. In 1876 he obtained the entrance scholarship in natural science at St. Bartholomew's Hospital, and entered upon the study of medicine. It is hardly too much to say that this step was taken as a *pis aller*. He looked forward with anything but satisfaction to the life of a medical practitioner, and when, in 1879, he was elected to the newly-created chair of zoology in the Owens College, he entered with delight upon a career devoted to the advancement of his favourite science.

As might have been expected from the friend and companion of Balfour his first work was embryological, and consisted of a series of papers on the Cranial Nerves, published in the *Journal of Anatomy and Physiology* and the *Quarterly Journal of Microscopical Science* between the years 1877 and 1881. Though in matters of detail these papers may need correction, and though the "Segmental Value of the Cranial Nerves" is as much open to discussion as it was when Marshall wrote his thesis, these memoirs were at the time solid contributions to our knowledge, and have furnished a basis upon which other men have wrought. The culmination of his work in this direction has been the great work on "Vertebrate Embryology," of which an appreciative notice appeared in these columns so recently that it is not needful to do more than allude to it.

In 1881 the dredging operations of the Birmingham Natural History Society gave him the opportunity of studying the Pennatulida, and in the following year a report upon these animals was issued under the joint authorship of himself and his father. In this and in his subsequent papers on the "Pennatulida of the *Porcupine* and *Triton* Expeditions," and of the "Mergui Archipelago," written partly alone and partly in conjunction with Dr. G. H. Fowler, he carefully elaborated the distinctions between the various forms of zooids and traced the relationships of the genera on morphological grounds. Strong reasons were adduced for dissenting from the classification propounded by Kölliker, though Marshall never considered that he had enough material at command to justify him in proposing an alternative arrangement. On the whole it is probable that these memoirs will form his most lasting contribution to zoological science.

A paper on "The Nervous System of Antedon," containing the results of an Easter vacation spent at Naples, was valuable as establishing beyond question the views of the Carpenters regarding the nervous function of the central capsule and axial cords of Crinoids, but it is still more interesting as an example of Marshall's clear and logical method.

Marshall was a born teacher; his mind was of that rare order which not only sees a problem clearly itself, but is cognisant of every step taken in understanding it, and hence is able to enter into the position of those who approach it for the first time, and to see where their diffi-

culties will lie. His lectures were illustrated not only by wall diagrams, prepared by himself, but by sketches on the blackboard drawn with the clear decided stroke of a master-hand whilst he was talking. He was second to none in appreciating the importance of drawing as a means of fixing the details of a structure upon the student's mind, and it was his custom to offer annually a prize for the best note-book produced by a member of the class.

In his own investigations it was his practice to begin with the illustrations, and in this way the whole of the figures in his "Vertebrate Embryology" were drawn before a line of the text was written. This power of clear exposition and his long experience as a teacher rendered him a singularly competent writer of text-books, as is evidenced by "The Frog," and "Practical Zoology," each of which has passed through several editions.

His powers as a teacher and his powers as an athlete rendered him extremely popular with the students; his advice was often sought and was valued because it was always candid, whilst his geniality and kindliness were such that his most outspoken criticism never gave offence.

It is no disparagement, however, to his powers as a scientific investigator and as a teacher, to say that his greatest distinction was his capacity for organisation, though this was as yet only known to those associated with him in administrative work; it is not too much to say that the great success which attended the Manchester meeting of the British Association was mainly due to his efforts as local secretary, whilst his services first as secretary and then as chairman of the Board of Studies rendered no small aid to the Victoria University in the early stages of its growth.

The University Extension movement in Lancashire and Cheshire loses one of its most ardent supporters. Though well aware of the necessary failings of this method of imparting instruction, he was firmly persuaded of its usefulness as a means of stimulating an interest in intellectual studies. He was an ideal Extension lecturer; his singularly lucid style enabled him to expound difficult biological problems to large popular audiences, whilst the truths he taught were indelibly impressed upon his audience by the striking and generally humorous language in which they were couched.

Marshall was elected a Fellow of the Royal Society in 1885, and served upon the Council for the year 1891–2. By his death the scientific world loses a conscientious and brilliant worker; the college and university a successful teacher and administrator; but what of those who are privileged to be his friends? He was a most stimulating influence in work, and a cheery companion in pleasure, whose geniality was never known to be ruffled by ill-temper or irritation. He concealed a deep seriousness beneath a jocular and almost boyish demeanour and phraseology, and whilst rejoicing in an unbounded flow of animal spirits himself, the sorrows of others touched him to the quick and called forth his practical sympathy. Science will progress and the college and university hold on their course but the place of our friend can never be taken by another.

NOTES.

It is with deep regret that we announce the death of Prof. Hertz, the eminent investigator whose work marks an epoch in the history of electrical science. The information comes as a surprise to us, and we are grieved that one from whom so much more might have been expected has been cut off in the prime of his life. The gap produced in the ranks of scientific investigators by his death will not readily be filled.

Prof. P. van Beneden must be added to the list of men of science who have recently passed away, and whose loss we mourn. He has just died at Louvain, at the age of ninety-three, but his works live and will always do honour to his name. He was a member of the Brussels Academy of Sciences, and had been professor at Louvain University for nearly sixty years.

We regret to record the death of Prof. Forchhammer, the well-known archæologist; of Prof. K. L. Michelet, Berlin at the age of ninety-two; of Dr. S. Guttmann, Geheimer Sanitäts-Rath, and editor of the *Medicinischen Wochenschrift*; and of Dr. L. Krahmer, Ordinary Professor of State Medicine in Halle University.

By the death of Dr. George Gordon, natural history in the north of Scotland has lost one of its most enthusiastic and oldest supporters. He died at the advanced age of ninety-two years, on December 12, after working nearly three-quarters of a century in the cause of science.

A committee of eminent men of science, art, and literature, with M. Pasteur at its head, has been formed in Paris for the purpose of raising the funds to erect a monument to the memory of the late Dr. Charcot.

Dr. R. Brauns has been appointed Professor of Mineralogy in the Darmstadt Technical High School.

A botanic garden and arboretum has been established at Buenos Ayres, by M. C. Thays.

Prof. G. Schweinfurth has started on his third botanical exploring visit to the Italian colony of Eritrea, on the Red Sea.

Prof. F. Delpino, of Bologna, has been appointed Director of the Botanic Garden at Naples, and Professor of Botany in the University.

One of the bequests in the will of Mr. A. Peckover, who died last month, is the sum of £100 to the Linnean Society.

Mr. F. E. Ives has been awarded the Elliott Cresson gold medal of the Franklin Institute for his system of colour photography, known as composite heliochromy.

The Society for the Encouragement of Industry in the Netherlands offer a prize equivalent to £30, and a gold medal, for the best memoir on the production of electricity by windmills. Intending competitors must send in their schemes before July 1, to the Secretary of the Society, Haarlem, Holland.

Electrical engineers have as yet been unable to perfect a system of working tramways electrically along crowded thoroughfares. Inventors have long been engaged endeavouring to overcome the difficulties, and as an incentive to them to throw themselves into their task with renewed vigour is an announcement in the *Times* that the Metropolitan Traction Company of New York City has offered the handsome award of about £10,000 for a system of street-car propulsion which will be superior or equal to the overhead trolley system, but without possessing the objectionable feature of the trolley for crowded thoroughfares.

The Committee on Science and the Arts of the Franklin Institute has issued a circular in which attention is directed to three awards under its control. The character and conditions of these awards are, briefly, as follows:—The Elliott Cresson Medal is of gold, and may be granted for some discovery in the arts and sciences, or for the invention or improvement of some useful machine, or for some new process, or combination of materials in manufactures, or for ingenuity, skill, or perfection in workmanship. The John Scott Legacy Premium and Medal (twenty dollars and a medal of bronze) is awarded for useful inventions. The Edward Longstreth Medal of Merit is

of silver, and may be awarded for useful invention, important discovery, and meritorious work in, or contributions to, science or the industrial arts. Full directions as to the manner and form in which applications for the investigation of inventions and discoveries should be made will be sent to interested persons on application to the Secretary of the Franklin Institute, Philadelphia.

In the annual report just issued by the University of Edinburgh, acknowledgment is made of several benefactions. We read that a legacy of £1000 has been bequeathed by the late Mrs Elizabeth Trevelyan for the foundation and endowment of a scholarship in engineering and mechanical and useful arts, and another bequest, by the late Mr. George Scott, of £1000 is destined for the foundation of a scholarship in arts. Since the close of the previous academic year a handsome bequest of £5000 by the late Mr. Alexander Low Bruce, to assist in the foundation of a chair of public health, has been intimated. Of very special interest and value is a collection of Arctic and other relics and curiosities, made by the late Dr. John Rae, the distinguished Arctic explorer, along with his bust, presented by his widow.

We would call attention to a new departure in University College. During the Easter Term Dr. L. E. Hill, Assistant Professor of Physiology, will give a practical course of instruction in psycho-physiology. The course will take the student methodically over the several senses, and familiarise him with the methods by which the new branch of science known as physiological-psychology or psycho-physics determines the precise manner in which sensation varies both quantitatively and qualitatively with variations of the stimulus, of the particular portion of the sensitive surface stimulated, and so forth. This is, we believe, almost the first attempt in this country to give to students systematic laboratory instruction in those experimental methods of investigating sense-phenomena which have already borne such valuable fruit in Germany and America. As supplying an exact and practical method of measuring sensibility the course should further prove valuable to teachers and others.

The increasing interest in psychological investigation in America is shown by the establishment of many psycho-physical laboratories, and by the formation last year of the American Psychological Association, which drew to Columbia College at its second meeting, December 27 and 28, a distinguished gathering of original investigators. The programme, besides the annual address of the president, Prof. G. T. Ladd, of Yale University, included the following papers :—The psychological standpoint, by Prof. G. S. Fullerton, University of Pennsylvania ; the case of John Bunyan, by Prof. Josiah Royce, of Harvard University ; some account of investigations at Columbia College, by Prof. Cattell ; same at Harvard University, by Prof. Münsterberg ; same at Yale, by Prof. Scripture ; experiments on visual memory, by Mr. H. C. Warren, of Princeton University ; Do we ever dream of tasting? by Prof. J. C. Murray, of McGill College, Montreal ; an early anticipation of Mr. Fiske's doctrine as to the meaning of infancy, by Prof. N. M. Butler, of Columbia College ; accurate work in psychology, by Dr. E. W. Scripture, of Yale University ; the problem of psychological measurement, by Mrs. G. H. Mead, of the University of Michigan ; the perception of magnitude and distance, by Dr. J. H. Hyslop, of Columbia ; pain and pleasure, by Mr. H. R. Marshall, of New York ; pain contrasts, by Prof. Edward Pace, of Catholic University, Washington ; the confusion of content and function in the analysis of ideas, by Prof. D. S. Miller, of Bryn Mawr College. Prof. James, of Harvard, was elected president for the ensuing year, and Princetown was named as the place of the meeting on December 27 and 28 of this year.

At the general meeting of the Association for the Improvement of Geometrical Teaching, to be held at University College, London, January 13, a new undertaking will be proposed by the Council, viz., the establishment of a journal of elementary mathematics, to appear three times a year, and to be specially devoted to such subjects as are usually taught in secondary schools.

A course of lectures on matters connected with sanitation will be given at the Sanitary Institute from January 26 to April 2. Among the lecturers are Sir Douglas Galton, Profs. Corfield, H. Robinson, A. W. Blyth, A. B. Hill, Dr. J. F. J. Sykes, Dr. A. Newsholme, and Dr. Hamer. The lectures have been arranged for the special instruction of those desirous of obtaining a knowledge of the duties of sanitary officers.

On Tuesday next (January 16), Prof. Charles Stewart, the newly elected Fullerian Professor of Physiology in the Royal Institution, will begin a course of lectures on "Locomotion and Fixation in Plants and Animals." The Friday evening meetings will begin on January 19, when Prof. Dewar will discourse on the "Scientific Uses of Liquid Air."

The annual general meeting of the Royal Meteorological Society will be held on January 17, when the report of the council will be read and the election of officers and council for the ensuing year will take place. The president of the society will deliver an address on "The Climate of Southern California."

A period of very severe weather has recently been experienced over these islands and the whole of Western Europe. On the 1st inst. an anticyclone lay over Scandinavia, and subsequently spread over the northern parts of this country, causing frost in many places, while snow showers occurred in England, accompanied by bitter easterly gales. For some days the frost and snow contiuued with increased intensity. The reports issued by the Meteorological Office show that on the morning of the 6th inst. the minimum temperature in South London fell to 13°, while on the previous day a temperature of 16° was recorded at Jersey, being 22° below the average minimum for January, and at Biarritz a reading of 14° was recorded on the 4th, being 20° lower than the reading at Bodö in Norway, within the Arctic Circle. Towards the end of the week the easterly gales had subsided in the south-east, but had spread to the northern parts of the kingdom. On Saturday morning the Meteorological Office reported a temperature of 5° in the Midland Counties and 6° in the centre of Ireland, but later information in the *Weekly Weather Report* shows that the absolute shade minimum recorded was minus 4° at Braemar and in the Midlands on that day. With reference to the temperature in the north-west of London, Mr. Symons recorded 13°·1 on the 5th, and a maximum temperature of 18°·4. His long series of observations shows that the severity of the night of the 4th and 5th was only exceeded three times in the last thirty-five years, viz. December 25, 1860, January 4, 1867, and January 17, 1881 (the day preceding the blizzard); while as regards the maximum, there has been only one day as severe during the same period, viz. January 4, 1867, when the temperature did not exceed 16°·9. The frost continued until the morning of the 8th, when a deep depression appeared off the south-west of Ireland, causing southerly winds and a considerable rise of temperature, and by Monday evening a thaw had set in generally.

Owing to delay at the Government Printing Office, Mr. H. C. Russell, the Government Astronomer for New South Wales, has only just been able to issue the results of rain, river, and evaporation observations made in that colony in 1892. In addition to the usual matter, the report contains the results of an attempt to determine the average rainfall of Australia. It will

be many years before the rainfall of Australia will be measured in all parts, but taking the values already obtained, and weighing them in proportion to the area of each colony in which they were made, the average annual value of the rainfall for the whole of the mainland of Australia comes out as 21·15 inches. Another matter which Mr. Russell has investigated is the effect of altitude upon temperature. In works of reference it is usually stated that a rise of 300 feet causes a fall of 1° Fahr., but this quantity must evidently vary with the locality. A comparison of the average temperatures at ten different places with that of Sydney, making an allowance at the rate of 1° Fahr. for a difference of one degree of latitude, gave 344 feet as the mean elevation required to produce a fall of 1° Fahr. The report concludes with an average rainfall map, constructed on the plan described in these columns on December 21; a new rainfall map for the year; a map showing the monthly distribution of rain over each square degree of New South Wales, and curves showing the height of the western rivers of that colony throughout 1892.

THE *Transactions* of the Devonshire Association for the Advancement of Science for 1893 contain a good account of the climate of Torquay, by A. Chandler, from trustworthy instruments. This health resort is favoured by a large amount of sunshine; dividing the year into two periods the summer has an average of 43·4 per cent., and the winter 30·5 per cent. of the possible amount. The average mean shade temperature is 50°·2, and the mean annual range 11°·4. The mean temperature of summer is 56°·5, and of winter 43°·8. The highest summer temperature during the year 1892 was only 78°·2, and the lowest winter temperature was 22°·4. The mean annual rainfall for twenty-five years, 1864–88, was 37 inches; June is generally the driest month, with an average of about 2 inches, and January the wettest, with a mean of a little over 4 inches. The prevalent winds are warm, being from south-west, and the town enjoys great freedom from storms. The observations are now organised and provided for by the Town Council.

WRITING upon the persecution of the Great Skua (Stercorarius Catarrhactes) in the *Annals of Scottish Natural History* for January, Mr. W. E. Clarke points out that a fact worth remembering in the history of those birds which have become extinct within the present century, is that their extermination had, in all instances, become an accomplished fact for several years before such was realised to be the case. In order to lead ornithologists to do something to prevent the Great Skua from a similar fate, Mr. Clarke gives an account of the persecution to which the bird is subject, and the wholesale stealing of its eggs. The evidence he brings forward shows that unless some measure of protection is immediately afforded to the Great Skua, this fine bird must soon cease to exist in Europe.

MISS E. A. ORMEROD contributes to the *Times* of Monday some observations on insect attacks upon crops and trees in this country during last year. She points out that the attacks of the year were much influenced by the exceptional deficiency of rainfall in the early half of 1893, from March onwards, and by other weather peculiarities. With regard to the imported locust appearances, the specimens which reached her alive proved to be of a South European species, which is not gregarious, and in its own country, though of large size, is known to do no appreciable damage. From the climatic requirements of locusts, therefore, and also from recorded experience, there does not appear to be any reason to fear even a possibility of locusts effecting a settlement in this country. It is pointed out by Miss Ormerod, however, that the presence of locusts in great quantities in fodder might be detrimental to the health of animals fed upon it.

ANOTHER note on locusts, more or less connected with the above, is contained in a statement recently issued by the Government of India (*Agricultural Ledger Series*, No. 2, 1893). Dr. Günther suggested to the Government, some time ago, that dried locusts might be used for insectivorous cage-birds and game-birds which are now reared at great expense upon ants' eggs. His letter was submitted to Mr. E. C. Cotes, of the Indian Museum, Calcutta, who has reported favourably upon it, but thinks there would be a difficulty in keeping up the supply from India at the present time. But though the invasion of India by the locust *Acridium peregrinum*, Oliv., is now practically at an end, Mr. Cotes says that Northern Africa, which was badly invaded in 1892 by the same insect, and is still infested, might offer a favourable ground for experiment.

THE silk-spider of Madagascar forms the subject of an interesting article in *Die Natur*, by Dr. Karl Müller. Its native name is Halabé, meaning great spider. This Halabé, or *Nephila Madagascariensis*, spins threads of a golden colour, and strong enough, according to Maindron, to hang a cork helmet by. The female spider may attain a length of 15 c.m., while the male does not exceed 3 c.m. A single female individual, at the breeding season, gave M. Camboué, a French missionary, some 3000 m. of a fine silken thread, during a period of about twenty-seven days. The thread was examined with a view to creating a new industry. Specimens tested at a temperature of 17° C. showed an elongation of 12·48 per cent. under a weight of 3·27 gr. Small textures woven of these threads are actually used by the natives for fastening flowers on sunshades, and for other purposes.

PROF. J. WIESNER, who has recently been studying the influence of artificial rain upon European and exotic plants, gave an account of his results at a recent meeting of the Vienna Academy. Some of the plants, called by Prof. Wiesner *ombrophobe*, can only for a short time stand continuous rain, and soon shed their leaves and decay. Others, called *ombrophil*, can stand it for months together. Plants growing in dry places are, as a rule, ombrophobe, but the reverse cannot be said of plants growing under wet surroundings. Leaves appear to gain in power of resisting rain as they develop, and to reach a climax in this respect at the period of their greatest vital activity, after which they lose much of that power. Leaves which can be wetted by water are usually ombrophil, those which cannot are usually ombrophobe, but in cases where leaves are both ombrophobe and easily wetted, they are extremely sensitive to rain. Prof. Wiesner thinks that ombrophobe leaves are enabled to resist the putrefactive action of water, especially at high temperatures, by certain antiseptic substances which they contain. The same may be said of hydrophil roots and submerged parts of aquatic plants.

THE edible lichen of Japan, known as "iwatake," is described in the *Botanisches Centralblatt* (1893, No. 45) by Dr. M. Miyoshi, under the name *Gyrophora esculenta*, sp.n. Its commercial value is due to the large amount which it contains of starch and of some gelatinous substance; and it is also extensively used in Japanese cookery as a condiment, having a pleasant flavour and being free from purgative properties. In some parts of Japan, especially the mountainous districts, it completely covers the moist granite rocks. After drying it is sent into the towns, and a large quantity is annually exported.

IN a recent number of the *Electrical World* (of New York), Lieut. F. Jarvis Patten has described a novel method of obtaining sinusoidal alternating currents of very low frequency. The apparatus, which the inventor calls a "liquid commutator," consists of a circular vessel, provided with two conducting electrodes fixed at the opposite extremities of a diameter. A con-

tinuous current is passed from one of these electrodes to the other, through the liquid contained in the vessel, the strength of the current being controlled by an internal resistance. A vertical spindle at the centre of the trough carries a revolving arm provided with conducting plates or electrodes at its extremities. These plates are insulated from one another, and are connected to two ring contacts carried by the central spindle. Two brushes bear on these rings, and convey the alternating current. By suitably altering the connections and electrodes, it is possible in the same manner to obtain multiphase currents. The author finds that the currents obtained are practically sinusoidal, and he suggests that they will be of considerable physiological use.

AT a recent meeting of the Société Française de Physique, M. Hurmuzescu showed some experiments on electrical convection in air. He finds that if you cause dissymmetry between the two discharging knobs of a Wimshurst electrical machine, by fixing a point to one of them, then, on placing a sensitive gold-leaf electroscope at a distance of about two metres, when the machine is worked, the discharging knobs being separated, the electroscope becomes charged. The electroscope becomes more highly charged when it is fitted with a point than when it has only a varnished ball at the end of its electrode. That the charge is not due to induction, but to convection through the air, is shown by the fact that the interposition of a metallic screen does not interfere with the effect, while if the electroscope is covered over by an insulating shade no electrification is observable. In addition, it is found that the charge on the electroscope is of the same sign as that of the terminal of the machine on which the point is fixed. The most marked and rapid results are obtained when the point on the machine is negatively electrified, while no effects are observed if the point is turned towards the plates of the machine.

AN account of Victor Schumann's successes in photographing rays of very short wave-lengths is given in No. 50, of the *Naturwissenschaftliche Rundschau*. These successes are entirely due to the elimination of absorption by the material used in the prisms and lenses and, what is especially noteworthy, of the layers of air intervening between the luminous source and the plate used for photographing the spectrum. This elimination has resulted in the exhaustive exploration of the hitherto doubtful ultra-violet region between 231·4 and 185·2 $\mu\mu$, and the annexation of the region down to 100 $\mu\mu$ to the known spectrum. For this it was necessary to get rid of the absorption due to the film of gelatine in which the sensitive silver salt was embedded, and this was accomplished by the substitution of a pure silver bromide plate. The camera, the spectroscopic apparatus, and the spark tube were all connected together and exhausted. The very first exposure on the hydrogen spectrum showed that the known radiations of that gas only represent a portion of its total radiance. The newly-traced portion turned out to be extremely rich in lines, with a maximum at about 162 $\mu\mu$, and consisted of fifteen groups of lines disposed pretty evenly, containing altogether about 600 lines, with intensities decreasing from the maximum in both directions, rapidly at first, and then very gradually. The wave-lengths of these lines are as yet undetermined. Provisionally, that of the smallest wave-length recorded is estimated at 100 $\mu\mu$. The spectra of aluminium, cadmium, cobalt, and other metals end at about 170 $\mu\mu$. A layer of normal air 1 mm. in thickness appears capable of absorbing all radiation of smaller wave-length than that. Dry gelatine absorbs eagerly all waves beyond 217 $\mu\mu$. Quartz is not suitable for prisms and lenses, and white fluor-spar is, so far, the only material that answers all requirements. The accurate determination of the new wave-lengths, the further investigation of the absorption due to air, and the further extension of the ultra-violet region, are the problems which Herr Schumann is now working at.

IN a note published in NATURE on July 20, attention was drawn to the manner in which the virulence of the typhoid bacillus may be increased by the products of other organisms being inoculated along with it into animals. In an elaborate paper, recently published in the *Annali dell' Istituto d'Igiene di Roma*, vol. iii. 1893, p. 117, Roncali shows how the virulence of the tetanus bacillus may be intensified by similar means. Thus an animal inoculated with this organism usually succumbs in three days; if, however, the soluble products of this bacillus be accompanied with those of some other organism, death ensues with tetanic symptoms in from 12–26 hours. It was also found that if by some means or other the power of resistance inherent in the animal was first diminished, the action of the tetanus toxine was greatly accelerated. This condition of diminished resistance was obtained by either first inoculating some other organism, or by introducing putrid infusions of meat or vegetables in themselves proved to be perfectly harmless to the animal in question. To further illustrate this point, symptoms of chronic tetanus were induced in animals by the inoculation of the soluble products of the tetanus bacillus obtained after from 3–4 days' growth. After from 8–10 days, if pathogenic or non-pathogenic organisms were introduced, the animals died in from 16–18 hours, whilst if they were not subsequently interfered with, they usually recovered in from 20–35 days. In the course of these investigations the interesting discovery was made that the bacillus of rabbit septicæmia, which is usually non-pathogenic to mice, may be rendered fatal to the latter by cultivation on agar-agar containing the soluble products of the tetanus bacillus. These experiments indicate how harmless saprophytes, such as the *b. prodigiosus*, may under given conditions become the servants of disease organisms, either by diminishing an animal's power of resistance, and so preparing the way for the entrance and work of pathogenic bacteria, or by hastening the lethal action of the latter by subsequent intrusion into the system of the infected animal.

WE have received three fascicules of the forthcoming volumes of the *Memoirs* (*Zapiski*) of the Russian Geographical Society. One of them contains D. Pokotilov's elaborate paper, "U-tai, its Past and Present," given to the description of the holy mountain of the Buddhists and its numerous monasteries. M. Pokotilov has followed the same route as Dr. Jos. Edkins ("Religion in China"), and also describes his journey from Pekin to the U-tai Mountain; but he also gives a detailed description of the Buddhist sanctuary, and the history of the development of Buddhist monasteries at this spot. The learned Russian scholar has utilised, moreover, the Chinese works devoted to the same subject. Taken in connection with Prof. Pozdneev's large work, "Sketches of the Life of Buddhist Monasteries and Buddhist Clergy," lately published in the *Memoirs* of the same Society (Ethnography, vol. xvi., 1887), M. Pokotilov's paper is a very valuable addition to the literature of the subject. Another fascicule of the *Zapiski* (Geography, vol. xv. No. 3) contains F. Schwartz's report on his astronomical, magnetical, and barometrical observations in Bokhara, Darvaz, Karateghin, and Russian Turkestan, made in 1886. A third fascicule (Statistics, vol. vii. No. 2) contains a detailed description of the Eritrean colony of Italy, by M. A. Troyansky.

THE Physical Society of London has just issued the third part of vol. xii. of its Proceedings.

THE first part is published of the new *Flore de France* (including Corsica and Alsace-Lorraine), by MM. G. Rouy and J. Foucaud.

WE have received No. 8 of the first volume of "Contributions from the U.S. National Herbarium." It is chiefly occupied by the description of American grasses, a large number of new species being described.

THE current number of the *Asclepiad* (vol. x. No. 39), edited by Sir B. W. Richardson, F.R.S., contains a good account of the works of Robert Boyle, and an autotype of that eminent investigator, from an engraving by R. Woodman.

THE second edition of Clowes' and Coleman's "Quantitative Analysis" (J. and A. Churchill) is about to be issued. The authors have thoroughly revised the book, and have introduced many recent modifications in processes, as well as new methods of analysis.

THE *Journal of the Royal Statistical Society* (part iv. vol. lvi.) has been received by us. It contains, among other papers, the presidential address delivered by Mr. Charles Booth in November last, and that given by Prof. Nicholson before the Economic Science and Statistical Section of the British Association at the Nottingham meeting.

WE have received "Eau Sous Pression," by M. F. Bloch, being a new volume in the Aide-Mémoire Series published by Gauthier-Villars, Paris. The early chapters in the book are devoted to enunciating hydrostatic and hydrodynamic principles, and stating the general theory of pumps, hydraulic rams, and accumulators. The subject is then treated from a practical point of view. The book contains thirty illustrations in the text, and does credit to an excellent series.

The Technical Instruction Committee of the County Council of Cumberland has issued a Directory of the Science and Art Classes, &c., under its control. We learn from this source that the average attendance of students at science classes held under the committee's jurisdiction is 1328. The subject that obtains the highest average is theoretical chemistry; then come agriculture, mathematics, plane and solid geometry, and physiography. Sound, light, and heat shows, by far, the lowest number of students, the average attendance for the whole county being only eight.

THE third volume (Series 3) of the *International Journal of Microscopy and Natural Science* has been published. The journal is the organ of the Postal Microscopical Society of London, which has for its object the circulation, study, and discussion of microscopic objects. The volume just received contains a large amount of information of use to microscopists, and several excellent papers, notably one on polarised light and its applications to the microscope, by Mr. G. H. Bryan, and a translation from *La Diatomiste* of Dr. Miquel's long article on the artificial cultivation of diatoms. The journal is well illustrated and does credit to the society the proceedings of which it reports. We have noticed two misprints, one on p. 8, where "Leek" is printed instead of Lick, and on p. 69 "Wills" is printed instead of Wells.

A USEFUL series of "Handbooks of Commercial Products" has been provided to the Imperial Institute by the Government of India. The books contain descriptions of the economic products of India, and among several of them recently received is one on Indian coal, in which a large number of facts concerning the geology and working of the coal districts are brought together. The iron resources and iron industries of the southern districts of the Madras Presidency are described in another of the handbooks, the account being accompanied by a plate showing the process adopted for the manufacture of wrought iron. The furnace employed is roughly circular in horizontal section, four feet high, two feet in diameter at the base, and only nine inches in diameter at the throat. Two other handbooks of interest to us summarise the present state of knowledge concerning the characters and occurrence of Indian micas and steatite.

A NUMBER of new reactions of formaldehyde, resulting in the preparation of several new compounds, are described by M. Henry in the *Bulletin de l'Académie Royale de Belgique*. This lowest number of the series of aldehydes, $HCHO$ or $O=CH_2$, appears to be endowed with very considerable chemical energy, as indicated by the readiness and frequently the violence with which it reacts with a large number of substances. The reactions now described are those which occur between formaldehyde and the primary and secondary amines. If a solution of methylamine is added to one of formaldehyde, in small portions at a time, a very energetic reaction occurs with evolution of so much heat that great loss occurs unless the vessel in which the operation is performed is surrounded by a freezing mixture. When the reaction is complete, the two substances being then present in equivalent quantities, the addition of solid potash precipitates methyl methylenamine, $H_2C=N-CH_3$, from the solution. This substance is readily purified, and proves to be a colourless mobile liquid, readily soluble in water, and boiling at 166°. At the temperature of a freezing mixture of ether and solid carbon dioxide it solidifies, and may be melted again at $-27°$. The ethyl compound may be similarly obtained, and is likewise a liquid; it boils at 207–208°, and melts after solidification by ether and solid carbon dioxide at $-45°$. Two molecular equivalents of dimethylamine react with even greater avidity in aqueous solution with one molecular equivalent of formaldehyde, and the reaction can only be safely carried out at a very low temperature. The product is tetramethyl methylenediamine $CH_2\begin{cases}N(CH_3)_2\\N(CH_3)_2\end{cases}$, a colourless and very mobile liquid which fumes strongly, dissolves in water, and boils at 85°. Ether and solid carbon dioxide will not solidify it. The tetraethyl compound, prepared in an analogous manner, is also a fuming liquid; it boils at 168°. All these compounds are insoluble in strongly alkaline liquids. They readily absorb water, like the amines, formaldehyde and the substituted ammonia being regenerated. A somewhat curious fact is observed in connection with the boiling-points. Methyl methylenamine $CH_2 : NCH_3$ boils at 166°, and methyl isocyanate $CONCH_3$, the analogous oxygen compound, at 43°; so that the replacement of two atoms of hydrogen by one of oxygen is accompanied in this case by a reduction of the boiling point by 123°. On the other hand, while the compound $CH_2\begin{cases}N(CH_3)_2\\N(CH_3)_2\end{cases}$ boils at 85°, the corresponding oxygen compound tetramethyl urea boils at 177°, nearly a hundred degrees higher.

IN a further communication to the *Bulletin* of the Belgian Academy, M. Henry describes a new mode of preparing halogen substitution products of the oxides (ethers) of the alkyl radicles. The monochlorine derivative of methyl ether $CH_2Cl{\cdot}OCH_3$ was prepared in 1877, by Friedel, by chlorination of the ether. It is now shown to be much more readily obtained by mixing a concentrated aqueous solution of formaldehyde with methyl alcohol and saturating the cooled solution with hydrochloric acid gas. The compound separates as a colourless liquid layer at the surface of the solution, and by distillation the pure substance is at once obtained, boiling at 60°. The monobromine derivative may be obtained in a precisely similar manner, and proves to be a pungently-fuming liquid, boiling at 87°. The iodine compound is also afforded by the analogous reaction with hydriodic acid, the pure liquid boiling at 124°, but, in addition, the di-iodine

derivative $CH_2I \cdot O \cdot CH_2I$ is simultaneously formed. Incidentally M. Henry observed that phenol reacts in a most violent manner with formaldehyde, great heat being evolved, and a remarkable porcelain-like substance being produced which is insoluble in all the usual solvents.

THE additions to the Zoological Society's Gardens during the past week include a Black-handed Spider Monkey (*Ateles ater*, ♀) from Eastern Peru, presented by Mr. L. Clarke; a Coot (*Fulica atra*) European, presented by Mrs. L. Spender; two Wedge-tailed Eagles (*Aquila audax*) from Australia, presented by Mr. F. W. Burgess; a Long-billed Butcher Bird (*Barita destructor*) from New Holland, deposited; a Salvin's Amazon (*Chrysotis salvini*) from South America, two Purple-capped Lories (*Lorius domicella*) from Moluccas, purchased; a Yak (*Poephagus grunniens*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

HARVARD COLLEGE OBSERVATORY REPORT.—In this, the forty-eighth annual report to the President of the University, Prof. Pickering, the director of the Astronomical Observatory of Harvard College, has a fine record of work to refer to, which has been carried out during the twelve months ending October 31, 1893. We make the following brief extracts from the accounts given of the various branches of work done in the several departments. The East Equatorial was on the whole worked by Mr. O. C. Wendell, and employed for the systematic observation of variable stars upon the system lately adopted. Photometric observations of Jupiter's satellites (twenty-five in number) were made; forty-eight series of wedge photometer observations (3354 measurements) for determining the brightness of 1118 stars occurring in the Durchmusterung, were also made. Among other uses of this instrument were the observations of comets, measurements with the polarising photometer, &c. The Meridian Circle has been, as usual, at work under the direction of Prof. W. Rogers, while good progress has been made in the reductions of the observations of the southern stars with the meridian photometer. The observing list for the latter observations contains about 6000 stars, and excluding the 4000 already contained in the Harvard Photometry, three quarters have now been made. Mr. W. Reed, with the West Equatorial, on eighty-seven evenings has made observations on variable stars (489), comparison stars (1318), and ten on the brightness of Comet Holmes.

With regard to the Henry Draper Memorial, Mrs. Fleming has given us, as usual, her list of stars with peculiar spectra, and her examination has resulted in the discovery of the new star in Norma. In addition to a classification of the 20149 spectra of stars for the new catalogue, work has been done with the 8-inch and 11-inch, resulting in the production of 2424 and 1037 photographs respectively. A most interesting series (213 photographs) of β Aurigæ has also been obtained.

In the Boyden Department, in addition to an expedition to observe the total solar eclipse in April last, important work was done by the 13-inch telescope, which was devoted to a study of the members of the solar system, an account of which has been previously referred to in this column. Prof. Bailey, the director of the third expedition, began work on April 4, and with an 8-inch and 13-inch telescope has obtained 1516 and 852 photographs with these two instruments respectively; some of these pictures show some very remarkable southern clusters. This observatory has also a meteorological station on Mount Chachani, 16,650 feet, the highest in the world; a second one has now been established on the volcano El Misti, at an elevation of 19,200 feet, with self-recording instruments. The Bruce photographic telescope will now be soon completed and ready for work, but the Bruce transit photometer has already made some progress towards the observations of tenth magnitude stars as standards for faint stellar magnitudes. Zodiacal phenomena have also been systematically observed. The new brick building for the thirty thousand glass photographic plates is finished, and the plates have been transferred. In his concluding remarks Prof. Pickering alludes to the difficulty, now becoming more and more significant every year, with regard to the observation of faint objects, owing to the increasing number of electric lights in the neighbourhood. An "electric tram" trouble seems also approaching a focus in the near future. We hope Prof. Pickering will successfully override these difficulties.

THE "GEGENSCHEIN."—In order to find out the origin of this peculiar phenomenon an effort has been made to obtain observations as nearly contemporaneous as practicable, and made at widely separated points. The distribution of light in the zodiac, and particularly of the slight maximum nearly opposite the sun, and known as "Gegenschein," or Counter-glow, has for some time past attracted the attention of astronomers, and we hope the present systematic attempt will be rewarded with successful results. Those cooperating in this work are Prof. Barnard, of the Lick, Prof. Bailey at Arequipa, Prof. Searle and Mr. Reed at Strafford, Vermont, and Mr. Douglass at Cambridge, U.S.A. Prof. Barnard, after describing the general appearance of this phenomenon (*Astr. Journal*, No. 308), besides noticing the change of form and its connection with a zodiacal band, finds that his observations show that the "Gegenschein" lags behind exactly opposite the sun, or, in other words, that its longitude is not quite 180° greater than that of the sun. His numbers are:—

From	$\lambda - \odot$.	β.	No. obs.
1883–1887	179·4 ...	+0°·4 ...	16
1888–1891	179·4 ...	+1°·3 ...	16
Sept. and Oct. 1893	179·6 ...	+0°·5 ...	22

His observations show no decided parallax to the object, but an appreciable north latitude, as seen from the value of β in the table above, will be noticed.

Prof. Barnard believes that the latitude of the "Gegenschein" and the lagging in longitude to be due to "atmospheric absorption, and that the object is exactly opposite the sun, and that it lies in the ecliptic, and if its centre were a definite point the position of the sun could be accurately determined from observations of the 'Gegenschein' by changing the sign of the declination and subtracting twelve hours from the Right Ascension."

GEOGRAPHICAL NOTES.

THE Arctic expedition planned by Dr. Stein, of the U.S. Geological Survey, as the first of a series for the gradual exploration of the Arctic regions from a base in Ellesmereland (see NATURE, vol. xlix. p. 18), is being actively prepared. According to Reuter's agency the command of the expedition has been offered to Baron Nordenskiöld, who has contributed £250 to its fund and has arranged by cable to keep a place open for a Swede on the staff. Dr. Stein has agreed to the latter proposal, and has stated that his first duty will be to search for the Swedish naturalists Björling and Kalstennius, whose tragic story has been briefly told in this column (p. 85). The possibility that the unfortunate party was able to reach the Eskimo of Ellesmereland and live with them for two years is very slight, but as long as the faintest chance remains it is satisfactory to find that arrangements are being made for a search and possible succour.

M. E. A. MARTEL, whose researches on the subterranean watercourses of France and Greece are well known, has been investigating the Adelsberg Grotto and other *karst* phenomena of Carniola, in company with Herr Putick. They were able to solve conclusively some points in the hydrology of the river Piuka, and found their way into parts of the Adelsberg cavern never before reached, proving that the whole length of the underground passages in connection with it is not less than 10 kilometres.

WITH the publication of vol. xix., dealing with South America, M. Elisée Reclus' great work, "Nouvelle Géographie Universelle: La Terre et les Hommes," has been completed. Twenty years have elapsed since the first volume was published, and these years have seen immense advances of geographical knowledge; but by the device of treating the less known continents at the end of the work, it has not fallen seriously out of date. Its great features are the philosophic grasp of the relation of man to his natural surroundings, and the working out of this relation for each continent and country. It is unfortunate that the state of public feeling on the continent makes it impossible for the University of Brussels to carry out the appointment of M. Reclus to a professorship there (see NATURE, vol. xlvii. p. 327 on account of his political views.

AT a meeting of the Royal Scottish Geographical Society, held last week at Edinburgh, with Prof. J. Geikie in the chair, to consider the question of Antarctic research, the following resolution by the council of the Society was read:—"That at this meeting, held for the discussion of Antarctic research, the Royal Scottish Geographical Society resolves to give its hearty support to the promotion of further exploration in the Antarctic. The Society's council is of opinion that at the present time a properly equipped Government expedition would, with the increased advantages of steam and modern appliances, have every prospect of successful explorations in the South Polar regions. The council is also convinced that the additions which might be made to our knowledge of climatology, terrestrial magnetism, geology, and natural history, would be of such practical scientific value as to fully justify the equipment of such an expedition at national expense. Towards the promotion of this object the council considers it desirable to submit a memorial on this subject to her Majesty's Government, and in this action they invite the cooperation of all the leading scientific societies of Scotland. To this end the Society appoints an Antarctic committee, consisting of Dr. John Murray, Prof. James Geikie, Dr. Buchan, and Mr. J. G. Bartholomew, together with the delegates of the other scientific societies, with instructions to draft such a memorial and take such steps towards the promotion of Antarctic exploration as is deemed desirable." A committee of the Royal Geographical Society was formed on the occasion of Dr. Murray's paper (NATURE, vol. xlix. p. 112), and has already been at work for some time with a view to bring the whole question of Antarctic exploration before Government. The course of action of this committee we understand to be the memorialisation of the Royal Society, requesting that body to take the lead in approaching the Government after ascertaining the feeling of all the leading scientific societies of the United Kingdom.

THE RISE OF THE MAMMALIA IN NORTH AMERICA.[1]

II.

Primitive Trituberculism.

There is a very general tendency among the vertebrates as a whole, fishes and reptiles as well as mammals, to form what are called "triconodont" crowns by the addition of lateral cusps to simple cones. In the mammals alone, these three cusps pass into higher stages of evolution, through what is called "trituberculy," in which these cusps form a triangle. The discovery of primitive widespread trituberculy by Cope was a great step forward. In looking over the odontographies of Cuvier, Owen, Tomes, and Baume, we find there is no suspicion of this common type around which the highly diverse mammalian molars centre. The molars of the clawed and hoofed mammals can now be compared, as we compare the hand or foot of the horse with that of the cat, because they spring from a common type. All the specialised mammalian series—ungulates, primates, carnivores, insectivores, rodents, marsupials—are found playing similar yet independent adaptive variations upon one type. We thus have a clue to the comparison of all molars with each other and with the reptile cones; take the human grinders, for example. The anterior outer cusps in the upper jaw, and the anterior inner cusps in the lower jaw, are homologous with each other and with the reptilian cone. Leaving aside for the moment Multituberculates and Monotremes, every known triassic, jurassic, cretaceous and basal eocene mammal (excepting Dicrocynodon) is in some stage of trituberculy; all the known cretaceous molars are simple triangles above; all later fossil mammals also converge to trituberculy, until in the lowest eocene every molar is tritubercular, and the early stages of divergence are so similar that it requires a practised eye to distinguish the molar of a monkey from that of a horse. Embryology supports the evidence of these fossil series. Thanks to the recent admirable researches of Röse and Tæcker, we find in the primates, ungulates and marsupials, that in the calcification of its dental caps every molar is heralded by *three cones placed in a triangle*, and in the lower jaw these three cones invariably appear in the same order (protocone, paracone, and metacone) in which they arose during the remote geological periods.

It is necessary to mention this overwhelming palæontological evidence, because "trituberculy" is still not universally recognised; Fleischmann and others have questioned the homologies of the upper and lower triangles, and two able writers, Röse and Forsyth Major, have independently proposed an opposition theory that "multituberculy" or "polybuny" is the mammalian archetype, the latter author believing trituberculy has become a "dogma." So far, however, from there being any decline of evidence, I am now able to add the Cretaceous mammalia to the tritubercular lists and bring forward evidence that the multitubercular molar instead of being primitive was derived from the tritubercular; moreover, all the researches I have been quoting tend to draw the mammals without exception into one of three great primary forms. The haplodont form, from which Dromotherium is just emerging in the Trias, is the oldest and nearest the reptiles; the triconodont, or three cones in line, was a predominating lower Jurassic type; the tritubercular, or three cones in a triangle (trigonodont, Rütimeyer), was the prevailing upper Jurassic and later form. The final predominance of the tritubercular over the others was due to its possibilities of mechanical adaptation to work of every kind—its *potential* in evolution. Upon the polyphyletic theory of the origin of the mammals here advocated, we must admit, first, the independent evolution of trituberculy in different phyla; and second, the branching off of several great groups in the pretritubercular stages.

The tendency of late research is to show that all stem mammals were related in their diphyodontism, in their dental formula, and in their primitive molar form. These features point, not to a succession, but to a unity of ancestry of the Monotremes, Marsupials, and Placentals.

Divergence of the Three Groups.

The discovery of the complete double series seems to have removed the last prop from the theory of the Marsupial ancestry of the placentals, for the peculiar mode of suppression of the second series in the Marsupials has been constant since the Purbeck; this difficulty is added to the structure of the jaw, the epipubic bones, the profoundly different mode of fœtal nutrition. None the less, any conclusion we can draw now as to the primary relations of the three great groups is more or less of a "Schwindelbau," and I put together the results of these later discoveries with a full realisation of the temporary character of present conclusions.

The Permian Sauro-Mammalia (Baur) with a multiple succession of simple conical teeth divided into: A, Theromorpha, which lost the succession and in some lines acquired a heterodont dentition and triconid single-fanged molars; B, Promammalia.

The hypothetical lower Triassic Pro-mammalia retained a double succession of the teeth; they became heterodont, with incipient triconid double-fanged molars; dental formula approximating 4. 1. 4–5. 8. They gave rise to three groups: I. The Prototheria which passed rapidly through the tritubercular into the multitubercular molars in the line of Multituberculates, and more slowly into trituberculy and its later stages in the ine of Monotremes. II. The Metatheria or Marsupials tended to suppress the second series of teeth, except those intercalated with the first; by this and by reduction the formula became 5. 1. 3. 4–6; the molars passed slowly through the triconodont into the typical tritubercular type. III. The Eutheria or Placentals divided early into a number of branches, in which there was heterodontism, but no uniform modification of succession.

We may distinguish four chief branches among these, as follows: (A) forms suppressing the second series in the molar region only, and acquiring a typical Eutherian dentition, 3. 1. 4. 3–4. 1. The Insectivores tended to partly suppress the anterior teeth of the second series or intercalate them with teeth of the first series; the molars became tritubercular. 2. The higher Placentals retained the succession of the first and second series as far back as the first molar; the molars entered rapidly into trituberculy and its higher stages. (B) forms retaining the double succession in part of the molar region, and retaining more of the primitive dentition, 4. 1. 4. 8. 3. The Edentates branched off from an early triconodont or tritubercular

[1] Continued from p. 238.

diphyodont stage, with numerous molars, and secondarily suppressed the first heterodont series, and established a numerous homodont second series. 4. The Cetacea also branched off from a diphyodont, heterodont stage, and secondarily established a numerous homodont first series, suppressing the second series.

Breaks and Links in the Mesozoic Fauna.

By our hypothesis all three sub-classes flourished together during the American Mesozoic; the Marsupials disappeared, then the Monotremes, and by the end of the basal Eocene the Placentals were in exclusive possession of the northern continent.

Although we have great reason to congratulate ourselves upon the rapid progress of discovery, there still remain great gaps in Mesozoic time between certain horizons, and in the lineal phyletic series of both the Mesozoic and Cenozoic. For a time standard we may take advantage of the remarkably constant evolution of the Plagiaulacidæ in the Mesozoic, and of the Equidæ in the Cenozoic—as certain invertebrates are made use of in older rocks. The grooves and tubercles of Plagiaulax and the cusps and styles of the horses are added with the precision of clockwork, and supposing that the rate of evolution has been about the same, we can approximately estimate both the periods of deposition and the intervals as follows.

PLAGIAULACIDÆ.

	Stonesfield.	Purbeck.	Laramie.	Puerco.	Cernaysian.
Number of Premolars,	?	4-3	2	2-1	1
Grooves on Premolars,	?	7-9	11-14	12-15	14
Molar Tubercles: outer; inner;	?	4:2	6:4	6:4	9:6

Estimating the geological intervals by dental evolution and faunal succession, there is first the great gap between the Trias of Microlestes and Dromatherium and the Jurassic of the Stonesfield slate; there is a relatively shorter interval, but still a considerable one between this and the Purbeck or Atlantosaurus beds. Then follows another long and very important interval between the Atlantosaurus beds and the Laramie (Upper Cretaceous). The gap between the Laramie and Puerco was relatively short, as indicated by the comparatively limited evolution both of the Plagiaulacids and Trituberculates. The Puerco was itself a long period in which the Plagiaulacids underwent considerable changes. Then follows an interval which it is most important to fill by future exploration, for between the Puerco and the Wahsatch the differentiation of the even and the odd-toed ungulates must have occurred. The Wahsatch proper does not mark a very extensive evolution of the forms it contains. It passes, after a slight break, into the base of the Bridger (Wind River), and then begins that splendid and almost uninterrupted succession of lake basins, terminating in the pliocene. I append a table, to be compared with that published by Marsh in his admirable address of 1877, and which exhibits the great progress of the last sixteen years.

THE SUCCESSION OF THE NORTH AMERICAN MAMMALIA.

PERIODS.	HORIZONS.	CHARACTERISTIC GENERA. NEW TYPES APPEARING.	TYPES BECOMING EXTINCT.
Post or Upper PLIOCENE.	EQUUS.	*Equus*, 5 species. Elephant, E. *primigenius*. Mastodon. Llamas. Camels, *Eschatius*. *Holomeniscus*. Elk, *Alces*. *Platygonus*. Sloths, *Mylodon*, *Glyptodon*. *Ursus*.	
True PLIOCENE.	BLANCO.	*Equus*, 3 species. *Mastodon*, 3 sp. Llamas, *Pliauchenia*, *Platygonus*. Sloth, *Megalonyx*. *Felidæ*. (?) *Hyænidæ*. *Mustelidæ*.	
MIOCENE. Upper.	LOUP FORK.	*Protohippus*, *Hipparion*. *Mastodon*. Rhinoceroses, *Aphelops*, 5 species. *Canidæ*. *Felidæ*. Rodents. Edentates. Camels and Llamas, *Procamelus*, *Protolabis*. Oreodons, 3 genera. Deer, *Blastomeryx*, *Cosoryx*.	Extinction of Oreodons and hornless rhinoceroses.
	DEEP RIVER.	*Protohippus*, *Anchitherium*. First Mastodons. Oreodons, *Cyclopidius*. *Chalicotherium*. Tylopoda.	Disappearance of Chalicotherium. Extinction of Creodonts, Hyænodons.
Middle.	JOHN DAY. WHITE RIVER.	*Miohippus*. Two-horned Rhinoceros, *Diceratherium*. *Hyopotamus*. Peccaries. Oreodons. Rodents. *Canidæ*, *Felidæ*. Tylopoda.	Extinction of Elotheres and Hyopotamus
	PROTOCERAS. (Upper.)	(?) *Miohippus*. Artionyx. Appearance of tragulines, Elotheres, *Hyopotamus*, pigs and peccaries, true dogs, cats, monkeys. *Leptauchenia*. *Colodon*. *Chalicotherium*, *Aceratherium*, *Protapirus*, *Agriochœrus*. Opossums. Tylopoda, *Pöebrotherium*. Creodonts, *Hyænodon*. Rodents. Insectivores.	Extinction of Hyracodons.
Lower.	OREODON. (Middle.)	*Mesohippus*. Amynodon.	Extinction of Amynodons.
	TITANOTHERIUM. (Lower.)	*Mesohippus*. Titanotherium.	Extinction of Titanotheres.
EOCENE.	UINTA.	*Epihippus*. *Amynodon*. Titanothere, *Diplacodon*. First Oreodons, *Protoreodon*. First Tylopoda, *Leptotragulus*. Tapirs. Hyracodons. Rodents. Creodonts, *Mesonyx*.	
Upper.	BRIDGER. WASHAKIE. (Upper.)	*Pachynolophus*. Appearance of Amynodons and horned Titanotheres. *Palæosyops*. *Hyrachyus*. *Triplopus*. *Achænodon*.	Extinction of Dinocerata, of some Creodonts.
	BRIDGER. (Middle.)	*Pachynolophus*. Appearance of Insectivora, Cheiroptera, Hyracodons. *Uintatherium*. *Palæosyops*. Creodonts.	Extinction of Tillodontia.
Middle.	WIND RIVER. (Lower.)	*Hyracotherium*. *Palæosyops*. Dinocerata. *Coryphodon*. *Phenacodus*.	Extinction of Coryphodontia and Condylarthra.
	WAHSATCH.	*Hyracotherium*. Appearance of Artiodactyls, Perissodactyls: tapirs, horses, titanotheres, lophiodons. First Rodents. First Coryphodons, Lemurs and Monkeys. Creodonts, 6 families, *Palæonictis*.	Extinction of Arctocyons.
Lower.	Interval.	(*Differentiation of modern clawed and hoofed placentals.*)	
	PUERCO.	*Ptilodus*, *Neoplagiaulax*, *Polymastodon*. Ancient types of Ungulates, Carnivores and Insectivores: Amblypoda, Condylarthra, Creodonta. Tæniodonta. Tillodontia. Lemurs.	Extinction of Multituberculates (? Monotremes).
	Interval.	(*Differentiation of ancient clawed and hoofed placentals.*)	Disappearance of Marsupials.
UPPER CRETACEOUS.	LARAMIE.	*Ptilodus*. *Bolodontidæ* (Multituberculates). *Thlæodon*, Trituberculate Placentals and Marsupials. Typical dentition.	
	Interval.		
MIDDLE JURASSIC.	Atlantosaurus.	*Ctenacodon*, *Plagiaulax*, *Bolodon*, Multituberculates (? Monotremes). Triconodonts (? Marsupials). Trituberculates (? Placentals). Primitive dentition.	
	Interval.		
UPPER TRIASSIC.	Chatham Coal Beds.	*Protodonta*, *Dromotherium*, *Microconodon*, primitive Triconodonts (? Monotremes).	

The general faunal succession is marked by the sudden appearance and disappearance of certain series and rise and fall of great groups. In the Trias appears the remarkable protodont or primitive-toothed Dromotherium; we cannot determine its order at present. We still have no American fauna corresponding to the intermediate Stonesfield of England. In the Jurassic Atlantosaurus beds the three supposed representatives of the Monotremes (multituberculates), Marsupials (triconodonts), and Placentals (trituberculates), appear in equal numbers; the latter are generally characterised by the primitive dental formula. In the Laramie the Multituberculates continue in great profusion, and the Marsupials and Placentals are also numerous.

The serial succession of the Trituberculates from the Mesozoic is still an unknown chapter; we are utterly unable to connect the Dromatheriidæ of the Trias, the Triconodontidæ, Amphitheriidæ and Amblotheriidæ of the Jura with each other, or with any Cretaceous or lower tertiary mammals. The serial relations of the Multituberculates, on the other hand, have been made much clearer by the discovery of the Laramie fauna. Cope and Marsh in this country, and Smith Woodward in England, have at last broken into the long barren Cretaceous. In studying the accurate figures published by Marsh and a large collection of teeth recently made for the American Museum by Wortman and Peterson, I find that this Laramie fauna is widely separated from the Jurassic in its general evolution, and as Gaudry, Lemoine, and Cope have observed, it approaches more nearly the basal Eocene of the Puerco and the Cernaysian of France. The Multituberculates of the Laramie include the Plagiaulacidæ, represented by Ptilodus, the form with two premolars, and Meniscoëssus, with two premolars and crescentic tubercles. Meniscoëssus has a smaller fourth premolar, and is found to lead off to the huge plagiaulacid Polymastodon of the Puerco. The only other Multituberculates found are those related to Bolodon of the Jurassic and Chirox of the Puerco. The other mammals of the Laramie range from the mouse to the opossum in size; they have superior molars of the simple tritubercular type—the low cusped or bunodent molar predominating in the upper jaw, and the tuberculo-sectorial in the lower. The dental formula is mostly the typical p. 4, m. 3. Yet, judging by the angular region of the jaws, we have here both Placentals and Marsupials. Some of the teeth remind us strongly of those in the Puerco; their determination, however, is very difficult, for the jaws and teeth are almost entirely isolated. From another exposure of the Laramie, Cope has recently found the remarkable type Thlæodon—remarkable because it is a highly specialised trituberculate of typical dentition with a jaw which bears resemblance to that of the Multituberculates and of Ornithorhynchus. There is no placental angle nor strong marsupial inflection. This raises the supposition that Thlæodon may be one of the persistent trituberculate Monotremes which we are now looking for.

In the Puerco or basal Eocene, a very marked change occurs, for the American fauna loses some of its cosmopolitan character, the multituberculates or monotremes die out and the marsupials are not found at all; in fact they do not reappear in North America until the Miocene.

Ancient and Modern Placental Differentiation.

The Puerco is essentially an archaic fauna and is to be regarded as the climax of the first period of placental differentiation, a culmination of the first attempts of nature to establish insectivorous, carnivorous and herbivorous groups. These attempts began in the Cretaceous, and some of the types thus produced died out in the Puerco, some in the Wahsatch and Bridger; only a few flesh-eaters survived to the Miocene. It is most important to grasp clearly the idea of this functional radiation in all directions of this old Puerco fauna, resulting in forms like the modern insectivores, rodents, bears, dogs and cats, monkeys, sloths, bunodont and selenodont ungulates, and lophodont ungulates. This was an independent radiation of placentals, like the Australian radiation of marsupials. What was the cause of the wide-spread extinction of these types? So far as the ancient clawed types are concerned, their teeth and feet seem to be as fully adaptive in many cases as those of the later unguiculates; the hoofed types were certainly inferior in tooth evolution, for all their molars evolved on the triangular basis instead of the sexitubercular; the most sweeping defect of both the clawed and hoofed types was the apparent incapacity for brain-growth, their bodies went on developing while their brains stood still. Thus the stupid giant fauna, the Dinocerata, which rose out o this period, gave way to the small but large-brained modern types. It is noteworthy that the latest survivors of this wreck of ancient life were the large-brained Hyænodons.

Some of the least specialised spurs of this radiation appear to have survived and become the centres of the second or mid-Tertiary radiation from which our modern fauna has evolved. Yet we have not in a single case succeeded in tracing the direct connection. To sum up, we find on the North American continent evidence of the rise and decline and disappearance of monotremes and marsupials, and two great periods of placental radiation, the *ancient radiation* beginning in the mesozoic, reaching a climax in the Puerco and unknown post-Puerco, and sending its spurs into the higher tertiary, and the *modern radiation* reaching its climax in the Miocene, and sending down to us our existing types.

Another Eocene centre was lower South America, which has of late dimmed the prestige of North America in yielding strange forms of life. One theory of this Patagonian fauna is that it was an independent centre of functional radiation like the Puerco and Australian, full of adaptive parallels, but not yielding to Europe or America any of their older types. But Ameghino, to whose energetic researches we are chiefly indebted, believes that he finds a lower Eocene life zone—a sort of *south polar* centre—which supplied both America and Europe. The Puerco he believes is no older than the Santacruzian, which in turn is very much older than the Parana and Pampean formations, which Burmeister has made so well known. This yields the *Homunculus Patagonicus* which parallels Cope's Anaptomorphus in presenting a dentition as advanced in reduction as that of man. Ameghino finds here the ancestors of the Macrauchenidæ; he believes the Homolodontotheridæ are the ancestors of the Chalicotheriidæ—thus deriving a buno-selenodont from a lophodont type; the Proterotheriidæ, he believes, replace the Condylarthra and Hyracotherium in the ancestry of the horses. Similarly the Microbiotheriidæ are the stem of the creodonts and carnivores. I cannot coincide with any of these views. The Multituberculates are far older and widely different from the Abderites to which Ameghino traces their ancestry. I fully concur with the opinion of Cope, Zittel, Scott and others that this fauna is of somewhat later age, that it was directly connected with Australia and somewhat later with North America, supplying us, as has always been supposed, with our sloths. I quote from a recent address by Scott:—

"The oldest mammals from South America are those from Patagonia, which Ameghino has referred to the Eocene, but which are more probably Oligocene or Miocene. This fauna is of extreme peculiarity and isolation; it is made up chiefly of edentates, rodents and ungulates of those very aberrant types known as Litopterna and Toxodontia, which are so widely different from the hoofed mammals of the northern hemisphere; together with some primitive forms of primates, creodonts and marsupials. The marsupials are of extraordinary interest, for they comprise not only forms allied to the opossums, but also to recent Australian forms such as Thylacinus, Dasyurus and Hypsiprymnus. This is a most unexpected fact, and seems to point unmistakably to a great southern circumpolar continent."

The Puerco thus remains the most extensively known and most productive lower Eocene centre, yet we have very slender threads of positive evidence to connect its fauna with the later placental radiation.

The Creodonts of Cope occupy the same relation to the modern insectivores and carnivores that the Condylarthra do to the ungulates. The American group has been recently enriched by the discoveries of Wortman, and the literature by the careful revision of Scott. This author has divided them into eight families, placing the forms which most resemble the Insectivora in the new family, Oxyclænidæ. These families illustrate superbly the same law of functional radiation later repeated in the placental and marsupial carnivores. The Mesonyx family presents some analogies to the Thylacines. The modern bears are paralleled in the Arctocyons, with their low tubercular molars; Wortman and myself, with fresh materials, have recently added Anacodon to this family, a genus which was doubtfully regarded by Cope as an ancient ungulate. The Cats and Hyænas are imitated in the Oxyænas and Hyænodons, some of the Miocene forms of which Scott

suggests developed aquatic habits; as above noted, some of this family acquired large brains, and persisted late into the Miocene. A still more remarkable likeness to the cats is exhibited in the Palæonictis family, which, unlike the Hyænodons, forms its sectorials out of exactly the same teeth as the true cats. The first American Palæonictis was found two years ago by Wortman, and this author and myself have suggested that this may be the long-sought ancestor of the Felidæ. The Civets are anticipated in the Proviverridæ; yet both Cope and Scott, the highest authorities on this subject, believe that the dog-like Miacidæ alone formed the connecting link between the Creodonta and the true Carnivora.

The foot structure of the ancient Puerco ungulates is still only partly known. Cope has divided these animals into the Amblypoda and Condylarthra. The Amblypoda are represented in the Puerco by a large form called Pantolambda, with selenodont triangular upper molars, and possibly by Periptychus, with bunodont triangular molars. The Pantolambda molars were, as Cope has shown, converted into those of Coryphodon, the great lophodont Amblypod of the Wahsatch, by a process exactly analogous to that in which the *anterior* half of a Palæotherium molar was formed, that is, they acquired outer and anterior crests but no posterior crests. This Coryphodon molar type was still later converted into the Uintatherium type by swinging around the outer crest into a transverse crest. I have recently made a careful study of the fore and hind feet of Coryphodon, and have found that while the fore-foot was subdigitigrade like that of the elephant, the hind-foot was fully plantigrade, the entire sole resting upon the ground. The relation or connection between the Bridger Dinocerata and these earlier Amblypoda is still unknown. The Puerco Periptychus left no descendants. The other ungulates of the Puerco were the Condylarthra, the primitive Phenacodontidæ, the supposed ancestors of the Artiodactyls and Perissodactyls. Much remains to be done to clear up this question.

Thus an immense number of problems still await solution, and demand the generous co-operation of European and American specialists in the use of similar methods of research, in the prompt publication of descriptions and figures, and in the free use of museum collections. I may be pardoned for calling general attention to the service which the palæontological department of the American Museum is trying to render in the immediate publication of stratigraphical and descriptive tables of western horizons and localities.

The Factors of Evolution.

A few words in conclusion upon the impressions which a study of the rise of the mammalia gives as to the factors of organic evolution. I refer also to recent papers by Cope, Scott, and myself.
